Notices

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

With respect to any drug or pharmaceutical products identified, readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors, assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

Preface

In 1983 the first edition of *Anesthesia and Co-Existing Disease* by Drs. Robert K. Stoelting and Stephen F. Dierdorf was published with the stated goal "to provide a concise description of the pathophysiology of disease states and their medical management that is relevant to the care of the patient in the perioperative period." Since then, five more editions have been published. The last two editions were published under our editorial leadership.

This seventh edition of *Anesthesia and Co-Existing Disease* continues the tradition of presenting new and updated medical information to the anesthesiology community. New chapters include those on sleep-disordered breathing and critical care medicine. The chapters on geriatric medicine and cancer medicine have major updates, but all chapters contain new information, refer to major medical society guidelines and recommendations that affect the practice of perioperative medicine, and contain many tables, figures, illustrations, and photographs to aid in understanding key concepts. We hope that our readers will continue to find this book relevant to the care of the patient in the perioperative period.

Roberta L. Hines, MD

CHAPTER 1

Sleep-Related Breathing Disorders

JEAN G. CHARCHAFLIEH

Scientific study of sleep in humans dates back only about a century, whereas the development of sleep medicine as a medical discipline dates back only about 50 years. Rapid eye movement (REM) sleep was first described in cats in 1957. The genetic mutation of narcolepsy was first described in dogs in 1999. The *clock gene* mutation was first described in mice in 2005, demonstrating that a mutation in the circadian system clock gene disturbed not only the sleep cycle but also energy balance, resulting in hyperphagia, hyperlipidemia, hyperglycemia, hypoinsulinemia, obesity, metabolic syndrome, and hepatic dysfunction. The term *sleep apnea syndrome* was first introduced in 1975. Prior to that the term *Pickwickian syndrome* was used. In 1974 one of the first cases of what would be considered *obstructive sleep apnea* (OSA) was described as a case of periodic nocturnal upper airway obstruction in an obese patient with normal control of breathing, a positional increase in upper airway resistance, and associated dysrhythmias (bradycardia and asystole) that resolved with tracheostomy, which was the treatment of choice at that time. In 1981 the treatment of OSA was advanced by the understanding of its pathophysiology and by demonstrating the therapeutic efficacy of continuous positive airway pressure (CPAP) in a patient with

severe OSA who was scheduled for tracheostomy but refused the surgery and elected to undergo the "experimental" therapy with CPAP.

PHYSIOLOGY OF SLEEP

Our current understanding of the wake/sleep state maintains that wakefulness is accomplished by a brainstem neuronal pathway known as the *ascending reticular activating system* (ARAS), which involves several neurotransmitters including acetylcholine, dopamine, norepinephrine, histamine, and 5-hydroxytryptamine. Sleep is maintained by inhibition of the ARAS via a hypothalamic nucleus known as the *ventrolateral preoptic* (VLPO) *nucleus.* This involves two neurotransmitters: γ-aminobutyric acid (GABA) and galanin. There is reciprocal inhibition between the ARAS and the VLPO nucleus. The neurotransmitter adenosine promotes sleep by inhibiting cholinergic ARAS neurons and activating VLPO neurons. The timing and duration of sleep are influenced by three factors: (1) sleep homeostasis, which involves buildup of the inhibitory neurotransmitter adenosine during wakefulness, (2) circadian homeostasis, which is regulated by a hypothalamic nucleus that provides GABAergic input to the pineal gland, and (3) environmental *zeitgebers* ("time-givers"), which include light, temperature, eating, body position, and environmental stimulation. Light is the most important zeitgeber. It provides input to the hypothalamus to suppress release of melatonin from the pineal gland, whereas darkness stimulates the release of melatonin, also known as "the hormone of darkness." In normal circadian rhythm, time of onset of release of melatonin under dim light conditions occurs about 2 hours before sleep onset. Temperature is another important zeitgeber. Falling core body temperature promotes falling to sleep, whereas rising body temperature promotes awakening. Caffeine inhibits sleep by blocking the effects of adenosine.

Sleep Stages

Electroencephalography (EEG) is an important method of studying wakefulness and sleep and defining sleep stages. The electrical activity of the brain can be categorized into three states: wakefulness, REM sleep, and non-REM (NREM) sleep. The latter can be further categorized into three stages: N1, N2, and N3, according to the progressive decrease in frequency and increase in amplitude of EEG waveforms. Muscle tone as measured by electromyography (EMG) is normal during wakefulness, decreased during NREM sleep, and abolished during REM sleep. In terms of vegetative functions and energy expenditures, REM sleep matches or exceeds that in awake levels and has been described as a state of an active brain in a paralyzed body.

Sleep occurs in all stages of human life, including in utero, but sleep duration and stage proportions differ according to age. Sleep stages are not equally distributed during the sleep period. Stage N3, also known as *slow wave sleep,* occurs during the first third of the night. REM sleep periods increase in duration and intensity as sleep progresses. REM sleep is defined by three electrical findings: (1) on EEG: low amplitude, mixed frequency waves; (2) on electromyography: low or absent muscle tone (atonia); and (3) on electrooculogram (EOG): rapid eye movements. *Tonic REM sleep* refers to REM sleep–associated muscle atonia. *Phasic REM sleep* refers, in addition to atonia, to phasic bursts of rapid eye movements, muscle twitches, sympathetic activation, and dreaming that is likely to be recalled upon awakening, unlike NREM dreaming, which is less likely to be recalled.

Physiologic Differences Between NREM and REM Sleep

NREM sleep *maintains homeostasis* and autonomic stability at low energy levels—that is, with a low basic metabolic rate and a decreased heart rate, cardiac output, and blood pressure. Hormonal secretion is maintained.

REM is considered a more primitive state of sleep. It *impairs homeostasis* and disrupts autonomic stability. REM-induced autonomic instability manifests as irregularity in heart rate, cardiac output, blood pressure, and tidal volume and suppression of cardiac and respiratory chemoreceptor and baroreceptor reflexes. REM sleep is associated with skeletal muscle *atonia* affecting all skeletal muscles including upper airway dilator muscles and intercostal muscles but with significant sparing of the diaphragm.

Respiratory Control During Wakefulness and Sleep

The brainstem respiratory control center consists of two groups of neurons: a dorsal respiratory group that promotes inspiration and a ventral respiratory group that functions as the respiratory pacing center. The ventral group contains μ-opioid receptors that inhibit respiration when they are activated by endogenous or exogenous opioids. The respiratory control center sends output to the phrenic nerve and the hypoglossal nerve and receives input from three areas of the body: (1) electrical input from the forebrain regarding sleep/wake state, sleep stage, and voluntary control of breathing; (2) chemical input from peripheral and central chemoreceptors regarding pH, $Paco_2$, and Pao_2; and (3) input via the vagus nerve from mechanoreceptors in the lungs and airway. REM sleep decreases all three aspects of breathing control to a greater extent than NREM sleep.

The transition from wakefulness to sleep can be associated with breathing irregularity, including periodic breathing and sleep-onset apnea. After this transition, sleep is usually associated with an increase in airway resistance and $Paco_2$ (2–8 mm Hg) and a decrease in Pao_2 (3–10 mm Hg), chemosensitivity, CO_2 production (10%–15%), tidal volume, and minute ventilation.

Effects of Aging and Disease on Sleep

Aging *decreases* the percentage of sleep in its slow wave portion and in the REM portion and the total time in bed during

which one is asleep (also known as *sleep efficiency*). Aging *increases* the time it takes to fall asleep (also known as *sleep latency*) and the incidence of daytime napping.

Disease states can also disrupt sleep quality and quantity and produce vicious cycles in which sleep disruption and the disease state exacerbate each other until the cycle is broken by treating the disease or the sleep disruption or both. Both acute pain (including postoperative pain) and chronic pain disorders (e.g., fibromyalgia, chronic fatigue syndrome) also disrupt the quality and quantity of sleep. Clinically, fibromyalgia and chronic fatigue syndrome manifest with insomnia, nonrefreshing sleep, excessive daytime sleepiness, and fatigue.

Cardiovascular System Physiology During NREM and REM Sleep

NREM sleep increases vagal and baroreceptor control of the cardiovascular system and results in sinus dysrhythmia through the coupling of respiratory activity and cardiorespiratory centers in the brain. REM sleep–induced loss of homeostasis results in irregularity and periodic surges in heart rate, blood pressure, and cardiac output, which can present clinical risk in patients with cardiopulmonary disease or those with underdeveloped cardiorespiratory systems, such as infants (which increases the risk of sudden infant death syndrome). Phasic REM sleep is associated with phasic increases in sympathetic activity, resulting in heart rate and blood pressure surges without a corresponding increase in coronary blood flow. This can result in *nocturnal angina* and nocturnal myocardial infarction. Tonic REM sleep is associated with increased parasympathetic activity, resulting in abrupt decreases in heart rate, including pauses, which in patients with a congenital long QT syndrome or Brugada syndrome can trigger multifocal ventricular tachycardia or even sudden unexplained nocturnal death.

Cerebral Blood Flow, Spinal Cord Blood Flow, and Epileptogenicity During NREM and REM Sleep

NREM sleep is associated with a decrease in cerebral blood flow and spinal cord blood flow, with maintenance of autoregulation. REM sleep is associated with regional increases in cerebral blood flow and impaired autoregulation. Phasic REM sleep periods increase in intensity and duration toward early morning, with resulting early morning surges in blood pressure that can lead to an increased risk of stroke in the early morning hours. OSA is also associated with early morning surges in blood pressure, increased vascular reactivity to P_{CO_2}, and increased intracranial pressure that can result in additional risk of early morning stroke.

NREM sleep is more epileptogenic than both wakefulness and REM sleep because of increased thalamocortical synaptic synchrony and neuronal hyperpolarization, which promote seizure propagation. REM sleep is least epileptogenic because of decreases in thalamocortical synaptic synchrony and interhemispheric neuronal connectivity and the presence of REM-induced muscle atonia.

Effects of Sleep on Energy Balance and Metabolism

Sleep and sleep deprivation are associated with hormonal changes that affect energy metabolism and other endocrine functions. Hormonal release can be regulated by sleep homeostasis, circadian rhythms, or both. There are sleep deprivation–related postprandial increases in both insulin and glucose to levels greater than would occur without sleep deprivation, which indicates insulin resistance. This might explain the association between sleep deprivation and insulin resistance and diabetes mellitus. Sleep deprivation–related thyroid stimulating hormone peak release indicates that sleep deprivation is a hypermetabolic state.

Effects of Drugs on Sleep

Drugs that affect the central nervous system, autonomic nervous system, or immune system may affect sleep architecture and cause sleep disorders. Many drugs are capable of these changes, and some are listed in Table 1.1. Alcohol, barbiturates, benzodiazepines, nonbenzodiazepine GABA receptor agonists such as zolpidem, opioids, acetylcholinesterase inhibitors such as donepezil (which is used to treat Alzheimer's disease), antiepileptic drugs, adrenergic α_1-agonists such as prazosin, adrenergic α_2-agonists such as clonidine, β-blockers such as propranolol, β-agonists such as albuterol, nonsteroidal antiinflammatory drugs, corticosteroids, pseudoephedrine, theophylline, diphenhydramine, tricyclic antidepressants, monoamine oxidase inhibitors, selective serotonin reuptake inhibitors, serotonin and norepinephrine reuptake inhibitors, serotonin antagonist and reuptake inhibitors, dopamine and norepinephrine reuptake inhibitors, antimigraine drugs (triptans), and statins can all cause sleep disruption and sleep disorders.

SPECIFIC SLEEP DISORDERS

Specific sleep disorders are disorders that manifest predominantly but not exclusively with sleep manifestations. They include disorders that manifest primarily as: (1) decreased sleep (insomnia), which is the most common type of sleep disorder, (2) increased sleep (hypersomnias), (3) abnormal sleep behavior (parasomnias), (4) disruptions of circadian rhythm, and (5) sleep-induced exacerbations of certain pathophysiologic problems such as sleep-related movement disorders and sleep-related breathing disorders (SRBDs).

Narcolepsy represents the loss of boundaries between the three distinct states of wakefulness, NREM sleep, and REM sleep. *Parasomnias* represent admixtures of wakefulness with either NREM sleep or REM sleep. The admixture of wakefulness with NREM sleep results in NREM parasomnias that include confusional arousal, sleep terror, and sleep acting

TABLE 1.1 Effects of Drugs on Sleep Architecture and Sleep Disorders

Drug	Effect on REM Sleep	Effect on Slow Wave Sleep	Effect on Sleep Disorder
Alcohol	↓		↑ Snoring and exacerbation of SRBD
Barbiturates	↓		
Benzodiazepines		↓	
Zolpidem			↑ NREM parasomnia
Opioids	↑ At high doses	↓	↑ Hypoxia with OSA
Prazosin	↑		Resolves nightmares
Clonidine			Induces nightmares
β-Blockers			↑ Daytime sleepiness, Induce nightmares
Corticosteroids			Insomnia Bizarre dreams
Caffeine		↓	
Amphetamine	↓	↓	Bruxism
Tricyclic antidepressants	↓		↑ Periodic limb movements, restless legs syndrome (RLS)
MAOIs	↓ To almost zero		
SSRIs	↓		↑ Periodic limb movements, RLS ↑ REM sleep without atonia
SNRIs			↑ Periodic limb movements, RLS REM sleep behavior disorder
Trazodone		↑	
Mirtazapine			↑ Periodic limb movements, RLS
Bupropion	↑		↓ Periodic limb movements
Antipsychotics		↓	↑ Periodic limb movements, RLS
Lithium	↓	↑	Sleep walking
Statins			Insomnia Sleep disruption

MAOIs, Monoamine oxidase inhibitors; *NREM,* non-REM sleep; *OSA,* obstructive sleep apnea; *REM,* rapid eye movement sleep; *SNRIs,* serotonin and norepinephrine reuptake inhibitors; *SRBD,* sleep-related breathing disorder; *SSRIs,* selective serotonin reuptake inhibitors.

(talking, walking, cooking, or eating). REM parasomnias include REM nightmares and REM sleep behavior disorder, which is REM sleep *without* the usual atonia, which allows physical enactment of dreams during REM sleep and can result in injury to self or others.

PATHOGENESIS OF SLEEP-RELATED BREATHING DISORDERS

Pathogenesis of Obstructive Sleep Apnea

The hallmark of OSA is sleep-induced and arousal-relieved upper airway obstruction. The pathogenesis of this airway obstruction is not fully understood. Comorbid conditions that are associated with increased prevalence rates for OSA include hypertension, coronary artery disease, myocardial infarction, congestive heart failure, atrial fibrillation, stroke, type 2 diabetes mellitus, nonalcoholic steatohepatitis (NASH), polycystic ovarian syndrome, Graves disease, hypothyroidism, and acromegaly. *Predisposing factors* include genetic inheritance, non-Caucasian race, upper airway narrowing, obesity, male gender, menopause, use of sedative drugs and alcohol, and cigarette smoking. Direct physiologic mechanisms involved in the pathogenesis of OSA include (1) anatomic and functional upper airway obstruction, (2) a decreased respiratory-related arousal response, and (3) instability of the ventilatory response to chemical stimuli.

Narrowing of the Upper Airway

Airway obstruction can be due to anatomic narrowing or to functional collapse of the airway or to both factors. The most common sites of upper airway obstruction are the retropalatal and retroglossal regions of the oropharynx. Obstruction can be due to bony craniofacial abnormalities or, more commonly, excess soft tissue, such as thick parapharyngeal fat pads or enlarged tonsils. Children have many reasons for anatomic upper airway narrowing, including the very common enlargement of tonsils and adenoids, as well as the much less common congenital airway anomalies. The latter include Pierre-Robin syndrome, Down syndrome, achondroplasia, Prader-Willi syndrome, Klippel-Feil syndrome, Arnold-Chiari malformation type II, maxillary hypoplasia, micrognathia, retrognathia, tracheomalacia, and laryngomalacia.

In adults, acromegaly, thyroid enlargement, and hypothyroidism are additional causes of narrowing of the upper airway. Mallampati developed a clinical classification of oropharyngeal capacity to predict difficult tracheal intubation, and this was later found useful in predicting the risk of OSA as well. For every 1-point increase in the Mallampati score, the odds ratio for OSA is increased by 2.5.

Graves disease can cause OSA by extraluminal compression of the upper airway, and thyroid mass lesions can cause snoring, stridor, or sleep apnea. Toxic goiter may "burn out," leading to hypothyroidism, which increases the risk of OSA by inducing obesity and macroglossia. Acromegaly increases the risk of OSA by maxillofacial skeletal changes, upper airway soft tissue enlargement (including tongue size), and obesity.

Functional collapse of the upper airway occurs when forces that can collapse the upper airway overcome the forces that can dilate the upper airway. *Collapsing forces* consist of intraluminal negative inspiratory pressure and extraluminal positive pressure. *Dilating forces* consist of pharyngeal dilating muscle tone and longitudinal traction on the upper airway by an increased lung volume, so-called tracheal tug. Excessive inspiratory efforts to help overcome upper airway obstruction can lead to even more upper airway collapse by generating excessive negative intraluminal pressure. The supine position enhances airway obstruction by increasing the effect of extraluminal positive pressure against the pharynx, which lacks any bony support. Sleep, particularly REM sleep, decreases muscle tone generally, including that of the upper airway, and decreases lung volume, which decreases the tracheal tug effect. Patients with OSA have a more collapsible upper airway with altered neuromuscular control. Their upper airway muscles have inflammatory infiltrates and denervation changes, which might decrease their ability to dilate the airway during sleep.

The respiratory-related arousal response is stimulated by (1) hypercapnia, (2) hypoxia, (3) upper airway obstruction, and (4) the work of breathing, which is the most reliable stimulator of arousal.

Obesity

Obesity is a risk factor for OSA in all age groups. A *10% increase* in body weight is associated with a 6-fold increase in the odds of having OSA and a 32% *increase* in the apnea-hypopnea index. A *10% weight loss* is associated with a 26% *decrease* in the apnea-hypopnea index. Besides affecting the size of subcutaneous cervical fat, obesity could be associated with increased amounts of fat in the tongue and larger parapharyngeal fat pads.

Genetic Factors

Genes can affect the pathogenesis of OSA by influencing the regulation of sleep, breathing, energy metabolism, and craniofacial anatomy; certain alleles have been found to be associated with OSA. Heredity as a factor in OSA development is suggested by familial aggregation of cases of OSA.

Pathogenesis of Central Sleep Apnea

Central sleep apnea (CSA) refers to sleep apnea that is *not* associated with respiratory efforts during the apnea event. This *absence of respiratory effort* could be due to instability of neural control of respiration, weakness of respiratory muscles, or both. Instability of respiratory control may include increased, decreased, or oscillating respiratory drive.

Primary/Idiopathic Central Sleep Apnea

Primary/idiopathic CSA has an unknown cause and manifests as periodic breathing with a cycle length composed of apnea plus the subsequent hyperpnea. There is then an oscillation between hyperventilation and apnea. Increased chemosensitivity to P_{CO_2} predisposing to respiratory control system instability may be the underlying pathogenesis.

Secondary Central Sleep Apnea

The most common form of secondary CSA is narcotic-induced CSA, which is encountered in up to half of patients using opioids chronically. It can manifest either as periodic Biot's breathing or irregular ataxic breathing. The latter is usually associated with significant hypoxia and prolonged apnea.

Central Sleep Apnea With Cheyne-Stokes Breathing

CSA with Cheyne-Stokes breathing was the first form of a sleep-related breathing disorder to be described. In 1818 John Cheyne described the periodic nature of breathing in an obese patient who suffered from a stroke and heart failure. He described the patient as:

> *A.B., sixty years, of a sanguine temperament, circular chest, and full habit of body, for years had lived a very sedentary life, while he indulged habitually in the luxuries of the table….The patient suddenly developed palpitations and displayed signs of severe congestive heart failure. The only particularity in the last period of his illness, which lasted eight or nine days, was in the state of respiration. For several days his breathing was irregular; it would entirely cease for a quarter of a minute, then it would become perceptible, though very low, then by degrees it became heaving and quick, and then it would gradually cease again. This revolution in the state of his breathing occupied about a minute…this symptom, as occurring in its highest degree, I have only seen during a few weeks previous to the death of the patient.*

Congestive heart failure, stroke, and atrial fibrillation are the three most common conditions during which CSA with Cheyne-Stokes breathing is encountered. It is postulated that a significant decrease in ejection fraction and consequent increase in circulation time is at least partially responsible for this condition. The pathophysiology of this form of periodic breathing is described in terms of its four cyclical components: hypopnea, apnea, hypoxia, and hyperventilation (Fig. 1.1).

Pathogenesis of Sleep-Related Hypoventilation Disorders

Sleep-related hypoventilation disorders can be primary or due to a comorbid illness. Primary forms are rare and include the obesity hypoventilation syndrome (OHS/

Pickwickian syndrome) and central alveolar hypoventilation syndrome/Ondine's curse. Comorbid forms are more common, since they are usually associated with (1) common respiratory diseases, such as chronic obstructive pulmonary disease (COPD) or the overlap syndrome (COPD plus OSA); (2) drug-induced respiratory depression; (3) neurologic disorders such as amyotrophic lateral sclerosis, spinal cord injury, or postpolio syndrome; (4) neuromuscular disorders; and (5) restrictive chest wall disorders such as kyphoscoliosis. The clinical features of OHS include: (1) marked obesity, (2) somnolence, (3) twitching, (4) cyanosis, (5) periodic respiration, (6) secondary polycythemia, (7) right ventricular hypertrophy, and (8) right ventricular failure/cor pulmonale. OHS is characterized by hypoventilation during wakefulness, which worsens in the supine position and during sleep.

Pathogenesis of Sleep-Related Hypoxemia Disorder

Sleep-related hypoxemia disorder is due to exacerbation of diurnal hypoxemia due to cardiopulmonary disease.

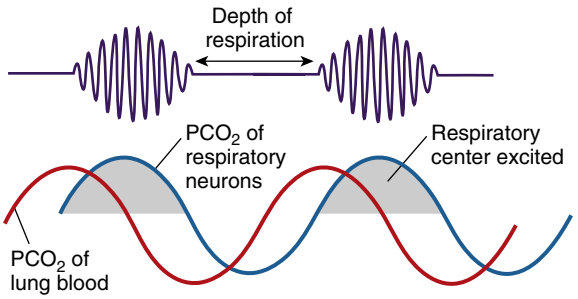

FIG. 1.1 Proposed underlying pathophysiology of Cheyne-Stokes breathing showing changing P_{CO_2} in the pulmonary blood *(red line)* and delayed changes in the P_{CO_2} of the fluids of the respiratory center *(blue line)*. (From Hall JE. Regulation of respiration. In: Hall JE, ed. *Guyton and Hall Textbook of Medical Physiology.* 13th ed. Philadelphia: Elsevier; 2016:539.)

PATHOPHYSIOLOGIC CONSEQUENCES OF SLEEP-RELATED BREATHING DISORDERS

Pathophysiologic Consequences of Obstructive Sleep Apnea

Cardiovascular Consequences (Table 1.2)

The pathophysiology of OSA is the result of three immediate events: apnea episodes, arousals, and increased respiratory effort. Direct and indirect effects of these events can interact and produce significant acute and chronic cardiac, neurologic, and metabolic morbidity and mortality.

Apneic and hypopneic episodes result in hypoxia, which can be prolonged and severe. OSA-induced hypoxia and reoxygenation cycles activate redox-sensitive genes, oxidative stress, inflammatory processes, the sympathetic nervous system, and the coagulation cascade, all of which can contribute to endothelial dysfunction and ultimately to systemic hypertension, pulmonary hypertension, atherosclerosis, right and left ventricular systolic and diastolic dysfunction, coronary artery disease, congestive heart failure, atrial fibrillation, stroke, and sudden cardiac death.

Arousal episodes lead to increased sympathetic system activity and decreased parasympathetic system activity, which results in increases in heart rate, left ventricular afterload, myocardial oxygen consumption, dysrhythmias, myocardial toxicity, and apoptosis. Arousal episodes lead to nonrestorative sleep and chronic sleep deprivation, which are also associated with increased sympathetic activity, inflammation, and a hypermetabolic state.

Increased inspiratory efforts can result in large swings in negative intrathoracic pressure, which are transmitted to the heart, lungs, and great vessels. The increase in transmural pressure in these structures can have multiple detrimental effects.

Swedish national data found that OSA is associated with an increased prevalence of coronary artery disease and that treatment of OSA reduces this risk. Untreated moderate to severe OSA is associated with an increased risk of repeat revascularization after percutaneous coronary intervention, and successful treatment of the OSA reduces this risk. OSA patients having coronary artery bypass surgery have an increased risk

TABLE 1.2 Cardiovascular Consequences of Obstructive Sleep Apnea

Immediate results	Hypoxemia, hypercarbia	Arousal	Reduced pleural pressure
Intermediate-term clinical consequences	Decreased oxygen delivery Oxidative stress Inflammation Hypercoagulability Pulmonary vascular constriction	Sympathetic activation Parasympathetic inactivation	Increased transmural pressure on heart and great vessels
Long-term clinical consequences	Cardiac dysfunction Endothelial dysfunction Increased right ventricular afterload Right ventricular hypertrophy	Tachycardia Hypertension Increased left ventricular afterload Increased myocardial oxygen consumption Myocardial toxicity Dysrhythmias	Increased right and left ventricular afterload Dysrhythmias, Aortic dilatation Increased lung water

of major adverse perioperative cardiac and cerebrovascular events. They also have a greater risk of significant dysrhythmias and atrial fibrillation in this setting.

Neurologic Consequences

The EEG changes of chronic sleep deprivation include overall slowing of the EEG, a decrease in deeper stages of sleep, and a compensatory increase in lighter stages of sleep. Psychomotor vigilance task testing demonstrates an increase in the number of lapses. OSA-induced disruption of sleep is associated with extensive daytime sleepiness, a decrease in cognition and performance (attention, memory, executive functioning), decreased quality of life, mood disorders, and increased rates of motor vehicle collisions. Caffeine consumption in OSA patients could be a behavioral compensatory mechanism to overcome their daytime sleepiness.

The mortality impact of OSA is evident in moderate to severe OSA. The economic impact is due to increased healthcare utilization, decreased productivity, and years of potential life lost. It is estimated that the yearly incidence of OSA-related motor vehicle accidents alone costs about $16 billion and 1400 lost lives. Treating all drivers with OSA with positive airway therapy (at a cost of ≈ $3 billion a year) would save about $11 billion and about 1000 lives.

Metabolic Consequences

With OSA, multiple mechanisms interact to produce metabolic derangements and disorders that can worsen OSA and produce a vicious cycle that must be broken by treating both of its elements. Pathophysiologic mechanisms of these metabolic derangements include hypoxic injury, systemic inflammation, increased sympathetic activity, alterations in hypothalamic-pituitary-adrenal function, and hormonal changes. The metabolic derangements include insulin resistance, glucose intolerance, and dyslipidemia. Metabolic disorders include type 2 diabetes mellitus, central obesity, and metabolic syndrome. OSA is encountered in 50% of patients with NASH and in 30%–50% of patients with polycystic ovarian syndrome.

Pathophysiologic Consequences of Central Sleep Apnea

Unlike OSA events, CSA respiratory events are *not* associated with increased respiratory effort and may terminate without arousal. Nevertheless, they are associated with hypoxia that can be severe and prolonged and can be associated with severe sleep disruption, including difficulty in establishing or maintaining a refreshing sleep state. The combination of sleep deprivation and hypoxia results in many associated cardiovascular, neurologic, and metabolic derangements.

Pathophysiologic Consequences of Sleep-Related Hypoventilation Disorders

About 90% of patients with OHS also have some degree of OSA, exacerbating their degree of hypoxia and hypercarbia. The major consequences of hypoxia and hypercarbia include pulmonary hypertension, cor pulmonale, and an increased risk of sudden unexplained nocturnal death. Patients with interstitial lung disease (e.g., interstitial pulmonary fibrosis) usually suffer from even more severe hypoxia and sleep disruption than those with COPD.

PREVALENCE OF SLEEP-RELATED BREATHING DISORDERS

Sleep-related breathing disorders are the second most common category of sleep disorders (after insomnia disorder) and are the most common sleep disorders encountered in sleep medicine clinics. OSA accounts for about 90% of sleep-related breathing disorders. Snoring is more common than OSA and is the most common reason for referral for a sleep study.

Prevalence of Obstructive Sleep Apnea

In 2014 the American Academy of Sleep Medicine (AASM) estimated that OSA affects at least 25 million adults in the United States. The proportion of OSA patients who are *not clinically diagnosed* is estimated to be roughly 80% among men and 90% among women. Patients with hypertension (including drug-resistant hypertension), type 2 diabetes mellitus, coronary artery disease, atrial fibrillation, permanent pacemakers, various forms of heart block, congestive heart failure, a history of stroke, and those coming for bariatric surgery have a much greater prevalence of OSA than the general population, and many of them are undiagnosed.

Prevalence of Central Sleep Apnea

CSA is not common. About 50% of cases of CSA are found in patients with congestive heart failure. Other common comorbidities include chronic renal failure, stroke, multiple sclerosis, neuromuscular disorders, chronic opioid use, and living at higher altitudes.

Prevalence of Obesity Hypoventilation Syndrome

OHS has an estimated prevalence of 0.15%–0.3% in the general population, with higher rates among women than men, probably owing to higher rates of obesity among women than men.

DIAGNOSIS OF SLEEP-RELATED BREATHING DISORDERS

The diagnosis of a sleep-related breathing disorder is based on criteria established by professional organizations, which also provide classifications of sleep disorders. The *International Classification of Diseases,* 10th edition (ICD-10), is developed by the World Health Organization and adopted by many government and billing organizations. The ICD-10 divides

TABLE 1.3 Physiologic Functions Studied During Polysomnography

Electroencephalogram to measure and evaluate sleep stages
Electrooculogram to measure eye movements
Chin electromyogram to measure muscle tone and the presence of REM sleep without atonia
Limb electromyogram to detect periodic limb movements and restless legs syndrome
Electrocardiogram to detect dysrhythmias
Upper airway sound recording to detect snoring
Nasal and oral airflow via a thermal sensor to detect apnea
Nasal airflow via a pressure sensor to detect hypopnea and arousals
Thoracoabdominal inductance plethysmography to detect respiratory efforts
Pulse oximeter to detect oxygen saturation/desaturation
Capnography to detect hypercarbia/hypoventilation
Body position sensor to note body position effects
Video recording or sleep technologist observation to detect parasomnias

TABLE 1.4 Rules for Scoring Respiratory Events During Polysomnography in Adults

Respiratory Event	Scoring Criteria
Obstructive apnea	Apnea for longer than 10 seconds with a ≥ 90% air flow reduction *despite respiratory effort*
Central apnea	Apnea for longer than 10 seconds with a ≥ 90% air flow reduction *without respiratory effort*
Hypopnea	A > 30% reduction in air flow for longer than 10 seconds associated with a ≥ 3% decline in oxygen saturation OR arousal
Hypoventilation	A 10-minute period with a P_{CO_2} > 55 mm Hg or a ≥ 10 mm Hg increase in P_{CO_2} to ≥ 50 mm Hg
Periodic breathing	≥3 consecutive cycles of Cheyne-Stokes breathing with a cycle length ≥ 40 seconds or ≥ 5 episodes of Cheyne-Stokes breathing in 2 hours

sleep disorders into six categories: insomnias, hypersomnias, parasomnias, circadian rhythm sleep disorders, sleep-related movement disorders, and sleep-related breathing disorders. The latter are further divided into four categories: OSA, CSA, sleep-related hypoventilation disorders, and sleep-related hypoxemia disorder.

Polysomnography

Polysomnography (PSG) can be used to differentiate CSA from OSA; assess its severity; detect associated hypoventilation and hypoxia; detect associated EEG, ECG, and limb movement events; and, when indicated, titrate positive airway pressure (PAP) therapy and perform follow-up assessments of any implemented therapy for the sleep-related breathing disorder. Rules for performing and interpreting PSG are published in the *AASM Manual for the Scoring of Sleep and Associated Events*. The manual covers the performance and interpretation of polysomnographic studies and home sleep apnea testing. The impact of these rules extends beyond performing and scoring an individual sleep study. These rules also affect diagnosis rates, which then affect calculations in epidemiologic studies and the implementation of individual and public health therapeutic interventions.

Standard PSG consists of simultaneous recording of multiple (7–12) physiologic parameters during a full night of sleep in a sleep laboratory with a sleep technologist in attendance (Table 1.3). It should contain 6 or more hours of recordings. The recorded PSG study is divided into 30-second periods called *epochs* for scoring purposes. During scoring, each individual epoch must be scored for sleep stage and any respiratory events such as apnea or hypopnea with or without obstruction, cardiac or limb events, and associated arousal. Respiratory events are scored if they last 10 seconds or longer (Table 1.4).

Sleep apnea testing can be done in several ways, each with a decreasing degree of complexity: level 1 testing is PSG; level 2 testing is unattended PSG done at home (rarely done); level 3 testing is home apnea testing in combination with an actigraph (a device that keeps track of movements as an assessment of sleep state); and level 4 testing uses 1–2 channels to monitor pulse oximetry and airflow. Level 4 testing is inadequate for a diagnosis of OSA, since it lacks information about respiratory effort.

Overnight home oximetry is an example of a level 4 home sleep apnea test. Data derived from this monitoring include the hourly frequency of a drop in Sao_2 by 3% or more and the T90, which is the total time spent with an oxygen saturation of less than 90%.

Morphometric Models

The association of anatomic risk factors with sleep apnea has been used to produce morphometric models to predict the likelihood of OSA. One morphometric model uses the triad of BMI, neck circumference, and oral cavity measurements and has a very high sensitivity and specificity. The oral cavity measurements include palatal height, maxillary intermolar distance, mandibular intermolar distance, and overjet (the horizontal distance between the edge of the upper incisors and the labial surface of the lower incisors). Note that overjet is not the same as overbite.

Questionnaires

Multiple tools in the form of questionnaires have been developed for screening populations for OSA. The *Epworth Sleepiness Scale* is used to assess excessive daytime sleepiness. The *Berlin Questionnaire* has three categories assessing snoring, sleepiness, and risk factors. The AASM developed a 10-item questionnaire to detect classic symptoms of OSA, and a 6-item checklist to identify patients who are at high risk for OSA. The American Society of Anesthesiologists (ASA) created an OSA

checklist with three categories: predisposing physical characteristics, history of apparent airway obstruction during sleep, and somnolence. Chung et al. used an acronym of some of the clinical features and risk factors of OSA to develop the *STOP-BANG* scoring model. The acronym *STOP* stands for **S**noring, **T**ired (daytime sleepiness), **O**bserved apnea, and high blood **P**ressure; and the acronym *BANG* stands for **B**MI 35 or greater, **A**ge 50 years or older, **N**eck circumference 40 cm (17 inches) or larger, and male **G**ender. Ramachandran et al. developed the *Perioperative Sleep Apnea Prediction* (P-SAP) score based on logistic regression analysis of surgical patient data. It has nine elements: age, male gender, obesity, snoring, diabetes mellitus type 2, hypertension, thick neck, Mallampati class 3 or greater, and reduced thyromental distance. (These questionnaires are available as appendixes to this chapter in Expert Consult online.)

Compared to PSG, most questionnaires demonstrate a trade-off between sensitivity and specificity, with a trend toward decreased specificity as the questionnaire score increases or the severity of OSA increases.

Criteria for the Diagnosis of Obstructive Sleep Apnea in Adults

Elements of the diagnosis of adult OSA include: (1) signs and symptoms such as extreme daytime sleepiness, fatigue, insomnia, snoring, subjective nocturnal respiratory disturbance, and observed apnea; (2) associated medical or psychiatric disorders such as hypertension, coronary artery disease, atrial fibrillation, congestive heart failure, stroke, diabetes mellitus, cognitive dysfunction, and mood disorders; and (3) predominantly obstructive respiratory events recorded during sleep center nocturnal PSG or during out-of-center sleep testing. The sum of apnea and hypopnea events per hour is defined as the *apnea-hypopnea index (AHI).* The sum of apnea, hypopnea, and arousal events is defined as the *respiratory disturbance index (RDI).*

Clinical findings of OSA in adults can be divided into three categories: (1) anatomic features; (2) nocturnal and diurnal signs and symptoms of OSA, including loud snoring, gasping, choking, breath-holding, breathing interruption, insomnia, restless sleep, nocturia, bruxism, morning headache, nonrefreshing sleep, fatigue, decreased cognitive and executive function, depression and irritability; and (3) commonly associated comorbidities.

Criteria for the Diagnosis of Central Sleep Apnea

Clinical findings of CSA can be divided into two categories: (1) nocturnal and diurnal signs and symptoms, including insomnia, frequent nocturnal awakenings with breath-holding, gasping or choking, mild snoring, breathing interruptions reported by bed partner, nonrestorative sleep, fatigue, and excessive daytime sleepiness; and (2) clinical findings of associated comorbidities, including neuromuscular diseases, congestive heart failure, stroke, end-stage renal disease, and opioid use. PSG will show apneic periods *without respiratory efforts.*

Criteria for the Diagnosis of Sleep-Related Hypoventilation Disorders

Clinical findings in patients with sleep-related hypoventilation disorders can be divided into three categories: (1) specific signs and symptoms of diseases associated with an increased likelihood of a hypoventilation disorder, including neuromuscular diseases such as amyotrophic lateral sclerosis, postpolio syndrome, and facial muscle weakness in muscular dystrophy; (2) clinical findings due to chronic hypoxia (plethora) and hypercapnia; and (3) clinical findings due to systemic complications of chronic hypoxia and hypercapnia, including polycythemia, right heart failure, liver congestion, and peripheral edema. The BMI is typically over 30 kg/m^2. PSG will demonstrate significant increases in P_{CO_2} during both wakefulness and sleep.

Criterion for the Diagnosis of Sleep-Related Hypoxemia Disorder

The criterion for diagnosis of this disorder is 5 minutes of a sleep-related decrease in oxygen saturation to less than 88% *with or without* hypoventilation.

TREATMENT OF SLEEP-RELATED BREATHING DISORDERS

Treatment of Obstructive Sleep Apnea

Because of its high prevalence rate and a general lack of diagnosis, the first step in management of OSA is detection. In cases of suspected obstructed sleep apnea, objective testing should be performed to confirm the diagnosis and assess its severity using PSG. Testing should be followed by patient education, initiation of treatment, and long-term follow-up to assess the effect of therapy.

Positive Airway Pressure Therapy

The PAP device is an air compressor that delivers air pressurized to specific levels. The device-patient interface can be a facemask, a nasal mask, or nasal pillows. PAP can be continuous (CPAP), bilevel (BiPAP) or autotitrating (APAP). The goal of PAP titration is to select the lowest airway pressure that would eliminate *all* respiratory events, including apneas, hypopneas, arousals, and snoring, so that the respiratory disturbance index decreases to less than 5 per hour, with acceptable oxygenation ($Spo_2 \geq 90\%$) and an acceptable mask leak level. Suggested mechanisms for the efficacy of PAP therapy include (1) increasing the pharyngeal transmural pressure *(pneumatic splint effect),* (2) reducing pharyngeal wall thickness and airway edema, (3) increasing airway tone by mechanoreceptor stimulation, and (4) increasing end-expiratory lung volume and producing a tracheal tug effect.

CPAP consists of a single fixed PAP that is maintained during both inhalation and exhalation. BiPAP consists of two fixed airway pressures: a higher inspiratory pressure and a lower expiratory pressure. The transition from inspiratory to expiratory pressure is based on the machine's detection of expiratory effort. BiPAP mode allows a lower expiratory pressure than what would be required with CPAP. BiPAP is an alternative therapy for OSA in patients requiring high levels of PAP who have difficulty exhaling against a fixed pressure, or who develop gastric distention from swallowing air while on CPAP, or who have co-existing central hypoventilation.

PAP therapy can be titrated either manually or automatically. Manual in-laboratory, PSG-guided, full night titration of fixed PAP is considered the norm. APAP titration consists of a single variable PAP that is maintained during both inhalation and exhalation, with variation from breath to breath according to the presence or absence of apnea, hypopnea, or snoring. APAP is an acceptable alternative for the treatment of uncomplicated moderate to severe OSA that is associated with snoring. APAP mode may improve patient adherence and may minimize the average airway pressure by allowing higher PAP during periods of greater obstruction, such as the supine position and REM sleep, and lower PAP during periods of lesser obstruction.

Expiratory positive airway pressure (EPAP) devices are disposable adhesive valves that direct exhaled airflow into small channels to increase resistance to exhalation and thereby create a degree of expiratory positive airway pressure.

Oral Appliance Therapy

Oral appliance therapy is considered second-tier treatment in the management of OSA. The most common forms of oral appliances for OSA treatment include mandibular advancement devices and tongue retaining devices. Mandibular advancement devices are usually custom-made devices that are fitted to the teeth like a mouth guard and act to advance and stabilize the mandible to increase upper airway capacity (Fig. 1.2). Tongue retaining devices advance and retain the tongue in an anterior position by holding it in a suction cup placed over the front teeth. ***(See video at aveotsd.com.)*** Mandibular advancement devices are more costly but have greater efficacy and patient

FIG. 1.2 An oral appliance (mandibular advancement device) for use in obstructive sleep apnea. A, Device. B, Natural occlusion of this patient. C, Mandibular advancement device in position. Note the forward movement of the lower teeth/jaw with this device. (From Marcussen L, Henriksen JE, Thygesen T. Do mandibular advancement devices influence patients' snoring and obstructive sleep apnea? A cone-beam computed tomography analysis of the upper airway volume. *J Oral Maxillofacial Surg.* 2015;73:1816-1826.)

compliance. Oral appliance therapy is indicated for the treatment of snoring, mild to moderate OSA, and selected cases of moderate to severe OSA, such as that due predominantly to the supine position or to a disproportionally large tongue relative to oral cavity capacity. This modality has been shown to be effective in reducing sleep interruption, daytime sleepiness, neurocognitive impairment, and cardiovascular complications. Side effects include excessive salivation, temporomandibular joint discomfort, and long-term occlusion changes.

Hypoglossal nerve stimulation uses a nerve stimulator that is implanted in the chest and has electronic sensing leads implanted between the internal and external intercostal muscles in the fourth intercostal space. These sensors detect breathing and signal the device to stimulate the hypoglossal nerve during inhalation, which results in enlargement of upper airway capacity. The system is turned on by the patient before going to sleep and turned off upon awakening.

Surgical Therapy

Surgical treatment of the airway in the form of tracheostomy is the oldest form of therapy for OSA and has a very high rate of efficacy. However, its invasiveness is its major deterrent. In adults, in whom anatomic causes of OSA are relatively uncommon, airway surgery treatment for OSA is considered third-tier therapy. These surgical procedures target soft tissue and bony tissue to enlarge airway capacity at the levels of the nose, palate, and/or tongue base and include maxillomandibular advancement, laser-assisted uvulopalatoplasty, uvulopalatopharyngoplasty, and palatal implants.

Bariatric surgery aims to restrict caloric intake or absorption or both. Bariatric surgery can be the sole therapy or an adjunctive treatment to PAP therapy in patients with morbid obesity associated with OSA or OHS. *Screening for OSA should be performed in all patients undergoing bariatric surgery.*

Medical Therapy

Adjunctive medical therapy for OSA can be used in combination with any of the other forms of OSA therapy: PAP, oral appliances, or surgery. These adjuncts include diet, exercise, positional therapy, avoidance of alcohol and sedatives before sleep, supplemental oxygen, and pharmacologic therapy, such as with a stimulant drug like modafinil (Provigil). Positional therapy consists of devices that discourage or prevent the patient from sleeping in the supine position.

Comorbid conditions should be treated. Thyroid disorders should be treated surgically, medically, or both as indicated. Acromegaly should be treated surgically, medically, or both as indicated. Bromocriptine and somatostatin therapy can reduce the apnea-hypopnea index in patients with acromegaly by 50%–75%. However, continued PAP therapy is usually required owing to persistent skeletal changes.

Treatment of Central Sleep Apnea

In CSA related to congestive heart failure, first-tier therapy consists of CPAP therapy and nocturnal oxygen supplementation. This can be augmented with BiPAP or drug therapy with acetazolamide and theophylline after medical optimization of congestive heart failure. Therapies for CSA associated with end-stage renal disease include CPAP, supplemental oxygen, use of bicarbonate during dialysis, and nocturnal dialysis.

Treatment of Sleep-Related Hypoventilation Disorders

Treatment of sleep-related hypoventilation disorders should enhance airway patency and ventilation, which is best achieved using *noninvasive positive pressure ventilation (NIPPV)* in one of three modes: (1) *spontaneous mode,* in which the patient cycles the device from inspiratory PAP to expiratory PAP; (2) *spontaneous timed mode,* in which a backup rate delivers PAP for a set inspiratory time if the patient does not trigger the device within a set period of time; and (3) *timed mode,* in which both the inspiratory time and respiratory rate are fixed. NIPPV is recommended for the treatment of hypoventilation due to *any* sleep-related breathing disorder.

PERIOPERATIVE CONSIDERATIONS IN PATIENTS WITH SLEEP-RELATED BREATHING DISORDERS

Management of sleep-related breathing disorders are a topic of special interest within the specialties of anesthesiology and sleep medicine. In 2011 this combined interest by the two specialties resulted in the establishment of the Society of Anesthesia and Sleep Medicine (SASM), which is an international society with a stated mission "to advance standards of care for clinical problems shared by Anesthesiology and Sleep Medicine, including perioperative management of sleep disordered breathing, and to promote interdisciplinary communication, education and research in matters common to anesthesia and sleep."

The prevalence of OSA among surgical patients is higher than the overall prevalence of 2%–4% in the general population. The perioperative period can exacerbate sleep-related breathing disorders because of (1) sleep deprivation due to anxiety, pain, alterations in circadian rhythms, and nursing interventions; (2) REM sleep rebound, which worsens OSA; and (3) the suppressant effects of anesthetics, sedatives, and analgesics on airway patency, respiratory drive, and arousal. The effect of sleep-disordered breathing on perioperative outcomes has been the subject of many observational studies and systematic reviews, with conflicting findings based on study population, examined outcomes, and study design. The evidence is, however, mostly negative.

PRACTICE GUIDELINES FOR PERIOPERATIVE MANAGEMENT OF PATIENTS WITH OBSTRUCTIVE SLEEP APNEA

The AASM, the ASA, and the Society for Ambulatory Anesthesia (SAMBA) have provided practice parameters for the

perioperative management of OSA patients. Algorithms for the perioperative management of OSA patients have also been developed by individual groups.

In 2003 the AASM published a statement for the perioperative management of OSA in which it indicated that the literature is insufficient to develop standards-of-practice recommendations, and that the statement was based on a consensus of clinical experience and published peer-reviewed medical evidence that, unfortunately, was scanty and of limited quality. The statement provided an introduction about OSA and listed the most common factors that contribute to increased perioperative risk in OSA patients, including: (1) increased risk of upper airway obstruction and respiratory depression due to effects of sedative, anesthetic, and narcotic medications; (2) decreased functional residual capacity (FRC) and decreased oxygen reserve due to obesity; and (3) the cardiopulmonary effects of OSA. It described the symptoms and signs of OSA, as well as a description of CPAP therapy, and provided a questionnaire and checklist for preoperative recognition of patients who are at high risk for OSA. The AASM also detailed recommendations for intraoperative and postoperative patient care, including transfer of care.

In 2006 the ASA developed comprehensive practice guidelines for the perioperative management of OSA patients and updated them in 2014. These guidelines provide a checklist for preoperative identification and assessment of OSA and detailed recommendations covering the areas of preoperative evaluation, considerations for inpatient versus outpatient surgery, preoperative preparation, intraoperative management, postoperative management, and criteria for discharge to unmonitored settings.

In 2012, SAMBA produced a consensus statement on preoperative selection of adult patients with OSA scheduled for ambulatory surgery, which concluded that patients *with known OSA* might be considered for ambulatory surgery *if* they were medically optimized and could use their CPAP postoperatively. Patients with *presumed OSA* could be considered for ambulatory surgery *if* they could be managed with *nonopioid analgesia perioperatively.*

The elements of the practice parameters for perioperative care of patients with OSA are noted in Table 1.5.

PERIOPERATIVE OPIOID-INDUCED RESPIRATORY DEPRESSION

The Anesthesia Patient Safety Foundation (APSF) made perioperative opioid-induced respiratory depression a top priority in 2006. In 2011 it held its second conference on this subject and focused on monitoring for this entity. The executive summary of this conference recommended that "all patients receiving postoperative opioid analgesia should have periodic assessment of level of consciousness and continuous monitoring of oxygenation by pulse oximetry," and if supplemental oxygen is provided, "continuous monitoring of ventilation by capnography ($PETCO_2$) or an equivalent method."

In 2009 the ASA provided "Practice Guidelines for the Prevention, Detection, and Management of Respiratory Depression Associated with Neuraxial Opioid Administration." These were updated in 2016. Like the APSF, the ASA recommended that all patients receiving neuraxial opioids be monitored for adequacy of *ventilation, oxygenation, and level of consciousness,* with increased monitoring for patients with high-risk conditions, including unstable medical conditions, obesity, OSA, concomitant administration of opioid analgesics or hypnotics by other routes, and extremes of age. They also recommended administering supplemental oxygen to patients with an altered level of consciousness, respiratory depression, or hypoxemia, and having resuscitative measures available as needed, including narcotic reversal drugs and NIPPV.

KEY POINTS

- Electroencephalography (EEG) is an important method of studying wakefulness and sleep and defining sleep stages. The electrical activity of the brain can be categorized into three states: wakefulness, rapid eye movement (REM) sleep, and non-REM (NREM) sleep. The latter can be further categorized into three stages: N1, N2, and N3, according to the progressive decrease in frequency and increase in amplitude of EEG waveforms. Muscle tone as measured by electromyography is normal during wakefulness, decreased during NREM sleep, and abolished during REM sleep.
- NREM sleep maintains homeostasis and autonomic stability at low energy levels—that is, with a low basic metabolic rate and a decreased heart rate, cardiac output, and blood pressure. Hormonal secretion is maintained.
- REM sleep impairs homeostasis and disrupts autonomic stability. REM-induced autonomic instability manifests as irregularity in the heart rate, cardiac output, blood pressure and tidal volume, and suppression of cardiac and respiratory chemoreceptor and baroreceptor reflexes. REM sleep is associated with skeletal muscle atonia affecting all skeletal muscles, including upper airway dilator muscles and intercostal muscles, but with significant sparing of the diaphragm.
- Specific sleep disorders are disorders that manifest predominantly but not exclusively with sleep manifestations. They include disorders that manifest primarily as: (1) decreased sleep (insomnia), which is the most common type of sleep disorder, (2) increased sleep (hypersomnias), (3) abnormal sleep behavior (parasomnias), (4) disruptions of circadian rhythm, and (5) sleep-induced exacerbations of certain pathophysiologic problems such as sleep-related movement disorders and sleep-related breathing disorders.
- The hallmark of obstructive sleep apnea (OSA) is sleep-induced and arousal-relieved upper airway obstruction.
- Functional collapse of the upper airway occurs when forces that can collapse the upper airway overcome the forces that can dilate the upper airway. Collapsing forces consist of intraluminal negative inspiratory pressure and extraluminal positive pressure. Dilating forces consist of pharyngeal

TABLE 1.5 Perioperative Management of the Patient With Obstructive Sleep Apnea

Potential Sources of Perioperative Risk	Perioperative Risk Mitigation
Lack of institutional protocol for perioperative management of sleep apnea patients	Develop and implement institutional protocol for perioperative management of sleep apnea patients.
Patients with a known diagnosis of obstructive sleep apnea (OSA)	Know sleep study results. Know the therapy being used: oral appliance, positive airway pressure (PAP) with settings (mode, pressure level, supplemental oxygen if any). Consult sleep medicine specialist as needed.
Patients without a diagnosis of OSA	Use a screening tool to determine the likelihood of OSA: AASM questionnaire, ASA checklist, Berlin questionnaire, or STOP-BANG questionnaire.
Inpatient versus outpatient surgery	Decisions based on institutional protocol containing factors related to: (1) patient, (2) procedure, (3) facility, and (4) postdischarge setting
Preoperative lack of optimization of therapy for OSA	Consult sleep medicine specialist to optimize therapy.
Preoperative sedative-induced airway compromise or respiratory depression	Use preoperative sedation only in a monitored setting.
Intraoperative sedative/opioid/anesthetic-induced upper airway compromise or respiratory depression during monitored anesthesia care (MAC)	Whenever possible, use topical, local, or regional anesthesia with minimal to no sedation. Continuous monitoring of ventilation adequacy Use of the patient's OSA therapy device during MAC with sedation Consider general anesthesia with a secured airway vs. deep sedation with an unsecured airway.
At risk for oxygen desaturation	Elevate head of bed to facilitate spontaneous ventilation/oxygenation. Preoxygenate sufficiently. Maintain oxygen insufflation by nasal cannula during endotracheal intubation.
Possible difficult mask ventilation or endotracheal intubation	Apply ASA Difficult Airway Algorithm, including the use of laryngeal mask airway, videolaryngoscope, fiberoptic bronchoscope, and transtracheal jet ventilation as indicated. Optimize head/neck position for mask ventilation and endotracheal intubation.
Potential difficulty with noninvasive blood pressure monitoring and/or increased risk for cardiovascular complications	Consider intraarterial catheter for blood pressure monitoring and blood sampling for arterial blood gases.
Postextubation airway obstruction in the operating room or postanesthesia care unit with associated risk of negative pressure pulmonary edema	Elevate the head of the bed. Extubate only after patient clearly meets objective extubation criteria. Maintain readiness for reintubation with the same device used during induction and expect that the difficulty of intubation will be greater than previously.
At risk for postoperative oxygen desaturation	Supplemental oxygen therapy Consider nasal airway. Consider PAP therapy (this can be initiated de novo in the postoperative setting).
Communication failure during transfer of care	Identify the patient's diagnosis of sleep apnea and its therapy. Alert staff about expected problems and their management.
Perioperative opioid-related respiratory depression due to opioids administered by neuraxial route, intravenous route with bolus injection, or via intravenous patient-controlled analgesia (IV-PCA)	Supplemental oxygen as needed Continuous electronic monitoring of oxygenation and ventilation Maintain patient's OSA therapy whenever possible; use home settings as a guide. Avoid background mode with IV-PCA. Consider opioid-sparing analgesic techniques (e.g., transcutaneous electrical nerve stimulation), and use nonopioid analgesics (e.g., NSAIDs, acetaminophen, tramadol, ketamine, gabapentin) whenever possible.
Postdischarge opioid-induced respiratory depression and/or exacerbation of OSA	Ensure companionship and a safe home environment for high-risk patients. Consult sleep medicine specialist to optimize sleep apnea therapy if needed.

ASA, American Society of Anesthesiologists; *NSAIDs,* Nonsteroidal antiinflammatory drugs.

dilating muscle tone and longitudinal traction on the upper airway by an increased lung volume, so-called tracheal tug.

- *Central sleep apnea* refers to sleep apnea that is not associated with respiratory efforts during the apnea event. This absence of respiratory effort could be due to instability of neural control of respiration, weakness of respiratory muscles, or both. Instability of respiratory control may include increased, decreased, or oscillating respiratory drive.
- Apneic and hypopneic episodes result in hypoxia, which can be prolonged and severe. OSA-induced hypoxia and reoxygenation cycles activate redox-sensitive genes, oxidative stress, inflammatory processes, the sympathetic nervous system, and the coagulation cascade, all of which can contribute to endothelial dysfunction and ultimately to systemic hypertension, pulmonary hypertension, atherosclerosis, right and left ventricular systolic and diastolic dysfunction, coronary artery disease, congestive heart failure, atrial fibrillation, stroke, and sudden cardiac death.
- Polysomnography can be used to differentiate CSA from OSA, assess its severity, detect associated hypoventilation

and hypoxia, detect associated EEG, ECG, and limb movement events, and, when indicated, titrate positive airway pressure (PAP) therapy and perform follow-up assessment of any implemented therapy for the sleep-related breathing disorder.

- Because of its high prevalence rate and a general lack of diagnosis, the first step in management of OSA is detection.
- Suggested mechanisms for the efficacy of continuous PAP therapy include (1) increasing the pharyngeal transmural pressure (pneumatic splint effect), (2) reducing pharyngeal wall thickness and airway edema, (3) increasing airway tone by mechanoreceptor stimulation, and (4) increasing end-expiratory lung volume and producing a tracheal tug effect.
- The perioperative period can exacerbate sleep-related breathing disorders because of (1) sleep deprivation due to anxiety, pain, alterations in circadian rhythms, and nursing interventions; (2) REM sleep rebound, which worsens OSA; and (3) the suppressant effects of anesthetics, sedatives, and analgesics on airway patency, respiratory drive, and arousal.
- To avoid opioid-induced respiratory depression, all patients receiving opioids, including neuraxial opioids, should be monitored for adequacy of ventilation, oxygenation, and level of consciousness, with increased monitoring for patients with high-risk conditions, including unstable medical conditions, obesity, OSA, concomitant administration of opioid analgesics or hypnotics by other routes, and extremes of age.

APPENDIX 1.1

Epworth Sleepiness Scale (ESS)

The ESS was developed in 1990 at Epworth Hospital in Melbourne, Australia, by Dr. Murray W. Johns to assess excessive daytime sleepiness (EDS). It has 8 questions, scored from 0–3 for each, to assess the likelihood of falling asleep in common daytime activities.

THE ESS

How likely are you to doze off or fall asleep in the following situations, in contrast to feeling just tired? This refers to your usual way of life in recent times. Even if you haven't done some of these things recently, try to work out how they would have affected you. Use the following scale to choose the most appropriate number for each situation.

Scale:

0 = would never doze
1 = slight chance of dozing
2 = moderate chance of dozing
3 = high chance of dozing

Situation:

1. Sitting and reading
2. Watching TV
3. Sitting inactive in a public place (e.g., a theater or a meeting)
4. As a passenger in a car for an hour without a break
5. Lying down to rest in the afternoon when circumstances permit
6. Sitting and talking to someone
7. Sitting quietly after a lunch without alcohol
8. In a car while stopped for a few minutes in traffic

INTERPRETING ESS SCORES

ESS score = 6 is the population norm.
ESS score ≥ 10 is considered abnormal and indicative of excessive daytime sleepiness.
ESS score ≥ 16 is commonly reported in patients with narcolepsy.
ESS score = 24 is considered a contraindication to operating a motor vehicle because it indicates a high chance of dozing in a car while stopped for a few minutes in traffic.

From Johns MW. A new method for measuring daytime sleepiness: the Epworth sleepiness scale. *Sleep*. 1991;14:540-545.

APPENDIX 1.2

Berlin Questionnaire (BQ)

The BQ was developed in 1996 at the Conference on Sleep in Primary Care in Berlin, Germany. It has 3 categories assessing snoring, sleepiness, and risk factors. A category is scored positive if it had ≥2 positive answers and the BQ is considered indicative of high risk for OSA if it has ≥2 positive categories.

Netzer et al. found that being high-risk according to the BQ group predicted an RDI ≥ 5 with a sensitivity of 0.86, a specificity of 0.77, a positive predictive value of 0.89, and a likelihood ratio of 3.79.

Berlin Questionnaire (BQ)

Height _____ m; Weight _____ kg; Age _____; Male/Female

CATEGORY 1. SNORING AND APNEA

Category 1 has 5 questions, with positive answers to each question being as follows:

1. Do you snore?
   Yes
2. If you snore, your snoring is:
   Louder than talking or can be heard in adjacent room
3. How often do you snore?
   ≥3–4 times a week
4. Has your snoring ever bothered other people?
   Yes
5. Has anyone noticed that you stop breathing during your sleep?
   ≥3–4 times a week

CATEGORY 2. DAYTIME SLEEPINESS

Category 2 has 4 questions, with positive answers to each question being as follows:

6. How often do you feel tired or fatigued after your sleep?
   ≥3–4 times a week
7. During your waking time, do you feel tired, fatigued, or not up to par?
   ≥3–4 times a week
8. Have you ever nodded off or fallen asleep while driving a vehicle?
   Yes
9. If yes, how often does this occur?
   ≥3–4 times a week

CATEGORY 3. RISK FACTORS

Category 3 has 3 questions, with positive answers to each question being as follows:

10. Do you have high blood pressure?
    Yes
11. Is your BMI > 30 or your neck collar size > 17 inches?
    Yes
12. Do you have a very small jaw or large overbite?
    Yes

From Netzer NC, Stoohs RA, Netzer CM, et al. Using the Berlin Questionnaire to identify patients at risk for the sleep apnea syndrome. *Ann Intern Med.* 1999;131(7):485-491.

APPENDIX 1.3

American Academy of Sleep Medicine Questionnaire for Exploring Obstructive Sleep Apnea

(YES/NO QUESTIONS)

1. People tell me that I snore.
2. I wake up at night with a feeling of shortness of breath or choking.
3. People tell me that I gasp, choke, or snort while I am sleeping.
4. People tell me that I stop breathing while I am sleeping.
5. I awake feeling almost as or more tired than when I went to bed.
6. I often awake with a headache.
7. I often have difficulty breathing through my nose.
8. I fight sleepiness during the day.
9. I fall asleep when I relax before or after dinner.
10. Friends, colleagues or family comment on my sleepiness.

HIGH RISK FOR OBSTRUCTIVE SLEEP APNEA CHARACTERISTICS

1. Male
2. BMI > 25 kg/m^2
3. Neck circumference (>17 inches in men, >16 inches in women)
4. Habitual snoring/gasping noted by bed partner
5. Daytime sleepiness
6. Hypertension

LOW RISK FOR OBSTRUCTIVE SLEEP APNEA CHARACTERISTICS

1. No snoring
2. Premenopausal
3. Thin

From Meoli AL, Rosen CL, Kristo D et al. Clinical Practice Review Committee, American Academy of Sleep Medicine. Upper airway management of the adult patient with obstructive sleep apnea in the perioperative period—avoiding complications. *Sleep*. 2003;26:1060-1065.

APPENDIX

1.4 ASA Checklist: Identification and Assessment of Obstructive Sleep Apnea in Adults

CATEGORY 1: PREDISPOSING PHYSICAL CHARACTERISTICS

a. BMI ≥ 35 kg/m^2
b. Neck circumference > 43 cm/17 inches (men) or 40 cm/16 inches (women)
c. Craniofacial abnormalities affecting the airway
d. Anatomic nasal obstruction
e. Tonsils nearly touching or touching the midline

CATEGORY 2: HISTORY OF APPPARENT AIRWAY OBSTRUCTION DURING SLEEP

Two or more of the following are present (if patient lives alone or sleep is not observed by another person, then only one of the following need be present):

a. Snoring (loud enough to be heard through a closed door)
b. Frequent snoring
c. Observed pauses in breathing during sleep
d. Awakens from sleep with choking sensation
e. Frequent arousals from sleep

CATEGORY 3: SOMNOLENCE

One or more of the following are present:

a. Frequent somnolence or fatigue despite adequate "sleep"
b. Falls asleep easily in a nonstimulating environment (e.g., watching TV, reading, riding in or driving a car) despite adequate "sleep"

SCORING

If two or more items in category 1 are positive, category 1 is positive.

If two or more items in category 2 are positive, category 2 is positive.

If one or more items in category 3 are positive, category 3 is positive.

High risk of obstructive sleep apnea: two or more categories scored as positive

Low risk of obstructive sleep apnea: only one or no category scored as positive

From Gross JB, Bachenberg KL, Benumof JL, et al. American Society of Anesthesiologists Task Force on Perioperative Management. Practice guidelines for the perioperative management of patients with obstructive sleep apnea: a report by the American Society of Anesthesiologists Task Force on Perioperative Management of Patients With Obstructive Sleep Apnea. *Anesthesiology*. 2006;104:1081-1093.

APPENDIX 1.5

Obstructive Sleep Apnea (OSA) Screening Tools

STOP QUESTIONNAIRE (4 YES-OR-NO QUESTIONS)

1. **S**noring: Do you snore loudly (loud enough to be heard through closed doors)?
2. **T**ired: Do you often feel tired, fatigued, or sleepy during the daytime?
3. **O**bserved: Has anyone observed you stop breathing during your sleep?
4. Blood **P**ressure: Do you have or are you being treated for high blood pressure?

High risk of OSA: Yes to 2 or more questions
Low risk of OSA: Yes to fewer than 2 questions

STOP-BANG SCORING MODEL (8 YES-OR-NO QUESTIONS)

1. **S**noring: Do you snore loudly (loud enough to be heard through closed doors)?
2. **T**ired: Do you often feel tired, fatigued, or sleepy during the daytime?
3. **O**bserved: Has anyone observed you stop breathing during your sleep?
4. Blood **P**ressure: Do you have or are you being treated for high blood pressure?
5. **B**MI: BMI more than 35 kg/m^2?
6. **A**ge: older than 50 years?
7. **N**eck circumference: >40 cm (17 inches)?
8. **G**ender: male?

High risk of OSA: Yes to 3 or more questions
Low risk of OSA: Yes to fewer than 3 questions

CHAPTER 2

Obstructive Respiratory Diseases

JING TAO, VIJI KURUP

Anesthesiologists commonly deal with patients with lung diseases and know that such patients are at an increased risk of perioperative pulmonary complications. There is increasing awareness of how these complications contribute to overall morbidity, mortality, and increased hospital length of stay. Perioperative pulmonary complications can also play an important role in determining long-term mortality after surgery. Modification of disease severity and patient optimization prior to surgery can significantly decrease the incidence of these complications.

Obstructive respiratory diseases can be divided into the following groups for discussion of their influence on anesthetic management: (1) acute upper respiratory tract infection (URI), (2) asthma, (3) chronic obstructive pulmonary disease (COPD), and (4) a miscellaneous group of respiratory disorders.

ACUTE UPPER RESPIRATORY TRACT INFECTION

Every year approximately 25 million patients visit their doctors because of a URI. The "common cold" syndrome results in about 20 million days of absence from work and 22 million days of absence from school, so it is likely there will be a population of patients scheduled for elective surgery who have an active URI.

Infectious (viral or bacterial) nasopharyngitis accounts for about 95% of all URIs, with the most common responsible viral pathogens being rhinovirus, coronavirus, influenza virus, parainfluenza virus, and respiratory syncytial virus (RSV). Noninfectious nasopharyngitis can be allergic or vasomotor in origin.

Signs and Symptoms

Most common symptoms of acute URI include nonproductive cough, sneezing, and rhinorrhea. A history of seasonal allergies may indicate an allergic cause of these symptoms rather than an infectious cause. Symptoms caused by bacterial infections will usually present with more serious signs and symptoms such as fever, purulent nasal discharge, productive cough, and malaise. Such patients may be tachypneic, wheezing, or have a toxic appearance.

Diagnosis

Diagnosis is usually based on clinical signs and symptoms. Viral cultures and laboratory tests lack sensitivity, are time and cost consuming, and therefore impractical in a busy clinical setting.

Management of Anesthesia

Most studies regarding the effects of URI on postoperative pulmonary complications have involved pediatric patients.

It is well known that children with a URI are at much higher risk of adverse events such as transient hypoxemia and laryngospasm if they are anesthetized while suffering a URI. However, there are limited data about the adult population in this regard. There is evidence to show an increased incidence of respiratory complications in pediatric patients with a history of copious secretions, prematurity, parental smoking, nasal congestion, reactive airway disease, endotracheal intubation, and in those undergoing airway surgery. Those with clear systemic signs of infection such as fever, purulent rhinitis, productive cough, and rhonchi who are undergoing elective surgery (particularly airway surgery) are at considerable risk of perioperative adverse events. Consultation with the surgeon regarding the urgency of the surgery is necessary. A patient who has had a URI for days or weeks and is in stable or improving condition can be safely managed without postponing surgery. If surgery is to be delayed, patients should not be rescheduled for about 6 weeks, since it may take that long for airway hyperreactivity to resolve. The economic and practical aspects of canceling surgery should also be taken into consideration before a decision is made to postpone surgery.

Viral infections, particularly during the infectious phase, can cause morphologic and functional changes in the respiratory epithelium. The relationship between epithelial damage, viral infection, airway reactivity, and anesthesia remains unclear. Tracheal mucociliary flow and pulmonary bactericidal activity can be decreased by general anesthesia. It is possible that positive pressure ventilation could help spread infection from the upper to the lower respiratory tract. The immune response of the body is altered by surgery and anesthesia. A reduction in B-lymphocyte numbers, T-lymphocyte responsiveness, and antibody production may be associated with anesthesia, but the clinical significance of this remains to be elucidated.

The anesthetic management of a patient with a URI should include adequate hydration, reducing secretions, and limiting manipulation of a potentially sensitive airway. Nebulized or topical local anesthetic applied to the vocal cords may reduce upper airway sensitivity. Use of a laryngeal mask airway (LMA) rather than an endotracheal (ET) tube may also reduce the risk of laryngospasm.

Adverse respiratory events in patients with URIs include bronchospasm, laryngospasm, airway obstruction, postintubation croup, desaturation, and atelectasis. Intraoperative and immediate postoperative hypoxemia are common and amenable to treatment with supplemental oxygen. Long-term complications have not been demonstrated.

ASTHMA

Asthma is one of the most common chronic medical conditions in the world and currently affects approximately 300 million people globally. The prevalence of asthma has been rising in developing countries, and this has been attributed to increased urbanization and atmospheric pollution.

Asthma is a disease of *reversible* airflow obstruction characterized by bronchial hyperreactivity, bronchoconstriction, and chronic airway inflammation. Development of asthma is multifactorial and includes genetic and environmental causes. It seems likely that various genes contribute to development of asthma and also determine the severity of asthma in an individual. A family history of asthma, maternal smoking during pregnancy, viral infections (especially with rhinovirus and infantile RSV), and limited exposure to highly infectious environments as a child (i.e., farms, daycare centers, and pets) all contribute to the development of asthma. A list of some stimuli that can provoke an episode of asthma are summarized in Table 2.1.

TABLE 2.1 Stimuli Provoking Symptoms of Asthma

Allergens
Pharmacologic agents: aspirin, β-antagonists, some nonsteroidal antiinflammatory drugs, sulfiting agents
Infections: respiratory viruses
Exercise: attacks typically follow exertion rather than occurring during it
Emotional stress: endorphins and vagal mediation

The pathophysiology of asthma is a specific chronic inflammation of the mucosa of the lower airways. Activation of the inflammatory cascade leads to infiltration of the airway mucosa with eosinophils, neutrophils, mast cells, T cells, B cells, and leukotrienes. This results in airway edema, particularly in the bronchi. There is thickening of the basement membrane and the airway wall may be thickened and edematous. The inflammatory mediators implicated in asthma include histamine, prostaglandin D_2 and leukotrienes. Typically there are simultaneous areas of inflammation and repair in the airways.

Signs and Symptoms

Asthma is an episodic disease with acute exacerbations interspersed with symptom-free periods. Most attacks are short lived, lasting minutes to hours, and clinically the person recovers completely after an attack. However, there can be a phase in which a patient experiences some degree of airway obstruction daily. This phase can be mild, with or without superimposed severe episodes, or much more serious, with significant obstruction persisting for days or weeks. *Status asthmaticus* is defined as life-threatening bronchospasm that persists despite treatment. When the history is elicited from someone with asthma, attention should be paid to factors such as previous intubation or admission to the intensive care unit (ICU), two or more hospitalizations for asthma in the past year, and the presence of significant co-existing diseases. Clinical manifestations of asthma include wheezing, productive or nonproductive cough, dyspnea, chest discomfort or tightness that may lead to air hunger, and eosinophilia.

Diagnosis

The diagnosis of asthma depends on both symptoms and signs and objective measurements of airway obstruction. Asthma is diagnosed when a patient reports symptoms of wheezing, chest tightness, or shortness of breath and demonstrates

TABLE 2.2 Most Clinically Useful Spirometric Tests of Lung Function

Forced expiratory volume in 1 sec (FEV_1): The volume of air that can be forcefully exhaled in 1 sec. Values between 80% and 120% of the predicted value are considered normal.

Forced vital capacity (FVC): The volume of air that can be exhaled with maximum effort after a deep inhalation. Normal values are ≈ 3.7 L in females and ≈ 4.8 L in males.

Ratio of FEV_1 to FVC: This ratio in healthy adults is 75%–80%.

Forced expiratory flow at 25%–75% of vital capacity ($FEF_{25\%–75\%}$): A measurement of airflow through the midpoint of a forced exhalation.

Maximum voluntary ventilation (MVV): The maximum amount of air that can be inhaled and exhaled within 1 min. For patient comfort, the volume is measured over a 15-sec time period and results are extrapolated to obtain a value for 1 min expressed as liters per minute. Average values for males and females are 140–180 and 80–120 L/min, respectively.

Diffusing capacity (D_{LCO}): The volume of a substance (carbon monoxide [CO]) transferred across the alveoli into blood per minute per unit of alveolar partial pressure. CO is rapidly taken up by hemoglobin. Its transfer is therefore limited mainly by diffusion. A single breath of 0.3% CO and 10% helium is held for 20 sec. Expired partial pressure of CO is measured. Normal value is 17–25 mL/min/mm Hg.

airflow obstruction on pulmonary function testing that is at least partially reversible with bronchodilators. Asthma severity depends on the clinical symptoms, the results of pulmonary function testing, and medication usage (Tables 2.2 and 2.3).

Pulmonary Function Testing

Forced expiratory volume in 1 second (FEV_1); forced expiratory flow, midexpiratory phase ($FEF_{25\%–75\%}$ [also called *maximum midexpiratory flow rate*]); and peak expiratory flow rate (PEFR) are direct measures of the severity of expiratory airflow obstruction (Fig. 2.1). These measurements provide objective data that can be used to assess the severity and monitor the course of an exacerbation of asthma. The typical asthmatic patient who comes to the hospital for treatment has an FEV_1 that is less than 35% of normal. Flow-volume loops show characteristic downward scooping of the expiratory limb of the loop. Flow-volume loops in which the inhaled or exhaled portion of the loop is flat help distinguish wheezing caused by airway obstruction (i.e., due to a foreign body, tracheal stenosis, or mediastinal tumor) from asthma (Figs. 2.2 and 2.3). During moderate or severe asthmatic attacks, the functional residual capacity (FRC) may increase substantially, but total lung capacity (TLC) usually remains within the normal

TABLE 2.3 Classification of Asthma Severity in Youths Older Than 12 Years and in Adults

Components of Severity		Classification of Asthma Severity (Youths ≥ 12 years of age and adults)			
		Intermittent	Persistent		
			Mild	Moderate	Severe
Impairment Normal FEV_1:FVC: 8–19 yr 85% 20–39 yr 80% 40–59 yr 75% 60–80 yr 70%	Symptoms	≤ 2 days/week	> 2 days/week but not daily	Daily	Throughout the day
	Nighttime awakenings	≤ 2x/month	3–4x/month	> 1x/week but not nightly	Often 7x/week
	Short-acting β_2-agonist use for symptom control (not prevention of EIB)	≤ 2 days/week	>2 days/week but not daily	Daily	Several times per day
	Interference with normal activity	None	Minor limitation	Some limitation	Extremely limited
	Lung function	• Normal FEV_1 between exacerbations • FEV_1 > 80% predicted • FEV_1:FVC normal	• FEV_1 < 80% predicted • FEV_1:FVC normal	• FEV_1 > 60% but < 80% predicted • FEV_1:FVC reduced 5%	• FEV_1 < 60% predicted • FEV_1:FVC reduced > 5%
Risk	Exacerbations (consider frequency and severity)	0–2/year >2/year → Frequency and severity may fluctuate over time for patients in any severity category. Relative annual risk of exacerbations may be related to FEV_1.			

From National Asthma Education and Prevention Program. *Expert Panel Report 3: Guidelines for the Diagnosis and Management of Asthma (EPR3)*. Bethesda, MD: National Heart, Lung, and Blood Institute; 2007.

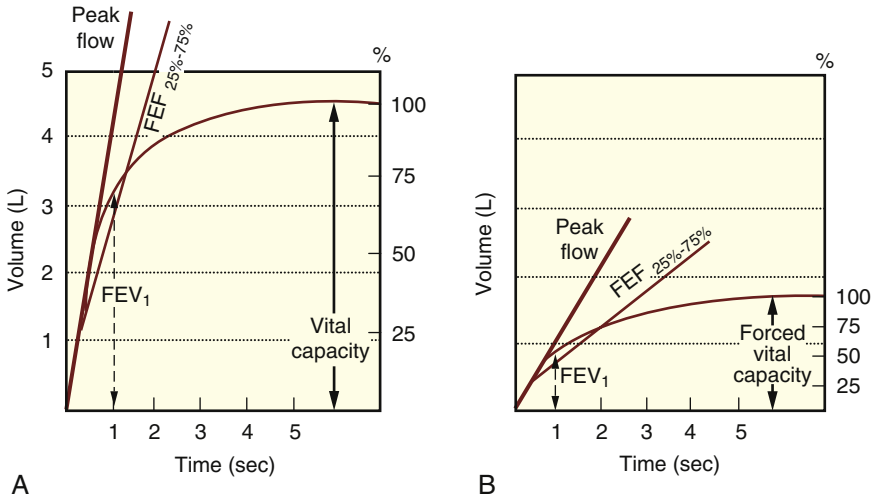

FIG. 2.1 Spirographic changes of a healthy subject (A) and a patient in bronchospasm (B). The forced expiratory volume in 1 second (FEV_1) is typically less than 80% of the vital capacity in the presence of obstructive airway disease. Peak flow and maximum midexpiratory flow rate ($FEF_{25\%–75\%}$) are also decreased in these patients (B). (Adapted from Kingston HGG, Hirshman CA. Perioperative management of the patient with asthma. *Anesth Analg.* 1984;63:844-855.)

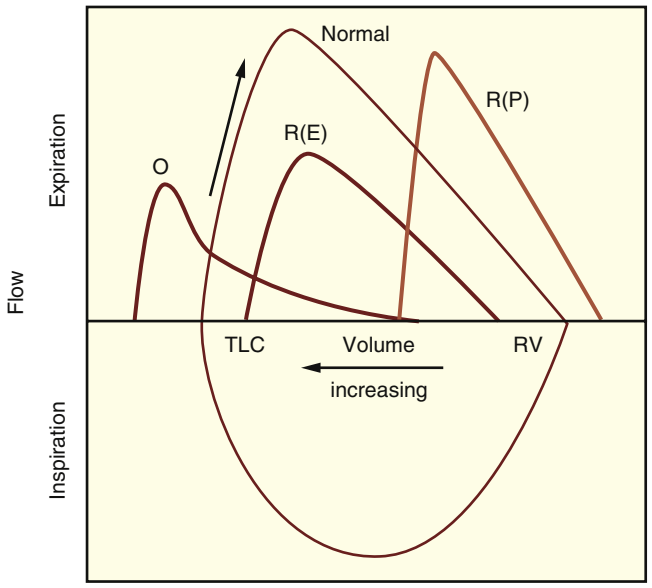

FIG. 2.2 Flow-volume curves in different conditions: obstructive disease, O; extraparenchymal restrictive disease with limitation in inspiration and expiration, R(E); and parenchymal restrictive disease, R(P). Forced expiration is plotted for all conditions; forced inspiration is shown only for the normal curve. By convention, lung volume increases to the left on the abscissa. The arrow alongside the normal curve indicates the direction of expiration from total lung capacity (TLC) to residual volume (RV). (Adapted from Weinberger SE. Disturbances of respiratory function. In: Fauci B, Braunwald E, Isselbacher KJ, et al., eds. *Harrison's Principles of Internal Medicine.* 14th ed. New York: McGraw-Hill; 1998.)

range. Diffusing capacity for carbon monoxide is not changed. Bronchodilator responsiveness provides supporting evidence if asthma is suspected on clinical grounds. In patients with expiratory airflow obstruction, an increase in airflow after inhalation of a bronchodilator suggests asthma. Abnormalities in pulmonary function test (PFT) results may persist for several days after an acute asthmatic attack despite the absence of symptoms. Since asthma is an episodic illness, its diagnosis may be suspected even if PFT results are normal.

Arterial Blood Gas Analysis

Mild asthma is usually accompanied by a normal Pao_2 and $Paco_2$. Tachypnea and hyperventilation observed during an acute asthmatic attack do not reflect arterial hypoxemia but rather neural reflexes in the lungs. Hypocarbia and respiratory alkalosis are the most common arterial blood gas findings in the presence of asthma. As the severity of expiratory airflow obstruction increases, the associated ventilation/perfusion mismatching may result in a Pao_2 of less than 60 mm Hg while breathing room air. The $Paco_2$ is likely to increase when the FEV_1 is less than 25% of the predicted value. Fatigue of the skeletal muscles necessary for breathing may contribute to the development of hypercarbia.

Chest Radiography and Electrocardiography

A chest radiograph in a patient with mild or moderate asthma even during an asthma exacerbation is often normal. Patients with severe asthma may demonstrate hyperinflation and hilar vascular congestion due to mucus plugging and pulmonary hypertension. Chest x-rays can be helpful in determining the cause of an asthma exacerbation and in ruling out other causes of wheezing. The electrocardiogram (ECG) may show evidence of right ventricular strain or ventricular irritability during an asthmatic attack.

The differential diagnosis of asthma includes viral tracheobronchitis, sarcoidosis, rheumatoid arthritis with bronchiolitis, extrinsic compression (thoracic aneurysm, mediastinal neoplasm) or intrinsic compression (epiglottitis, croup) of the upper airway, vocal cord dysfunction, tracheal stenosis, chronic bronchitis, COPD, and foreign body aspiration. Upper airway obstruction produces a characteristic flow-volume loop (see Fig. 2.3A). A history of recent trauma, surgery, or tracheal

TABLE 2.4 Short-Acting Bronchodilators Used for Immediate Relief of Asthma

Drug	Action	Adverse Effects
Albuterol (Proventil) Levalbuterol (Xopenex) Metaproterenol Pirbuterol (Maxair)	β_2-Agonist: stimulates β_2 receptors in tracheobronchial tree	Tachycardia Tremors Dysrhythmias Hypokalemia

intubation may be present in patients with upper airway obstruction mimicking asthma. Congestive heart failure and pulmonary embolism may also cause dyspnea and wheezing.

Treatment

Historically, treatment of asthma has been directed at preventing and controlling bronchospasm with bronchodilator drugs. However, recognition of the consistent presence of airway inflammation in patients with asthma has resulted in some changes in the pharmacologic therapy of asthma. There is now an emphasis on preventing and controlling bronchial inflammation as well as treating bronchospasm. Asthma treatments can be classified by their role in asthma management and by the timing of their effects (i.e., immediate relief or long-term therapy) (Tables 2.4 and 2.5).

Serial determination of PFTs can be useful for monitoring the response to treatment. When the FEV_1 improves to about 50% of normal, patients usually have minimal or no symptoms.

Status Asthmaticus

Status asthmaticus is defined as bronchospasm that does not resolve despite treatment and is considered life threatening. Emergency treatment of status asthmaticus consists of intermittent or continuous administration of β_2-agonists. β_2-Agonists inhaled via a metered-dose inhaler can be administered every 15–20 minutes for several doses without significant adverse hemodynamic effects, although patients may experience unpleasant sensations resulting from adrenergic overstimulation. Continuous administration of β_2-agonists by nebulizer may be more effective for delivery of these drugs to relieve airway spasm. Intravenous (IV) corticosteroids are administered early in treatment, because it takes several hours for their effect to appear. The corticosteroids most commonly selected are hydrocortisone and methylprednisolone. Supplemental oxygen is administered to help maintain arterial oxygen saturation above 90%. Other drugs used in more intractable cases include magnesium and oral leukotriene inhibitors. Studies on the use of IV magnesium sulfate indicate that it may significantly improve lung function and reduce the rate of hospital admission in children. The National Asthma Education and Prevention Program Expert Panel always has the most recent evidence-based guidelines for treatment of asthma on their website (http://www.nhlbi.nih.gov/about/org/naepp/).

Measurements of lung function can be very helpful in assessing the severity of status asthmaticus and the response to treatment. Patients whose FEV_1 or PEFR is decreased to 25% of normal or less are at risk of developing of hypercarbia and respiratory failure. The presence of hypercarbia (defined as a $PaCO_2 > 50$ mm Hg) despite aggressive antiinflammatory and bronchodilator therapy is a sign of respiratory fatigue that requires tracheal intubation and mechanical ventilation. The pattern of mechanical ventilation can be particularly important in the patient with status asthmaticus. The expiratory phase must be prolonged to allow for complete exhalation and

TABLE 2.5 Drugs Used for Long-Term Treatment of Asthma

Class	Drug	Action	Adverse Effects
Inhaled corticosteroids	Beclomethasone Budesonide (Pulmicort) Ciclesonide Flunisolide Fluticasone (Flovent) Mometasone Triamcinolone	Decrease airway inflammation Reduce airway hyperresponsiveness	Dysphonia Myopathy of laryngeal muscles Oropharyngeal candidiasis
Long-acting bronchodilators	Arformoterol (Brovana) Formoterol Salmeterol	β_2-Agonist: stimulates β_2-receptors in tracheobronchial tree	Therapy with just long-acting bronchodilators can cause airway inflammation and an increased incidence of asthma exacerbations. Should not be used except with an inhaled corticosteroid
Combined inhaled corticosteroids + long-acting bronchodilators	Budesonide + formoterol (Symbicort) Fluticasone + salmeterol (Advair)	Combination of long-acting bronchodilator and inhaled corticosteroid	
Leukotriene modifiers	Montelukast (Singulair) Zafirlukast (Accolate) Zileuton (Zyflo)	Reduce synthesis of leukotrienes by inhibiting 5-lipoxygenase enzyme	Minimal
Anti-IgE monoclonal antibody	Omalizumab (Xolair)	Decreases IgE release by inhibiting binding of IgE to mast cells and basophils	Injection site reaction Arthralgia Sinusitis Pharyngitis Headache
Methylxanthines	Theophylline Aminophylline	Increase cAMP by inhibiting phosphodiesterase, block adenosine receptors, release endogenous catecholamines	Disrupted sleep cycle Nervousness Nausea/vomiting, anorexia Headache Dysrhythmias
Mast cell stabilizer	Cromolyn	Inhibit mediator release from mast cells, membrane stabilization	Cough Throat irritation

cAMP, Cyclic adenosine monophosphate; *IgE,* immunoglobulin E.

to prevent self-generated or intrinsic positive end-expiratory pressure *(auto-PEEP).* To prevent barotrauma, some recommend a degree of permissive hypercarbia. When the FEV_1 or PEFR improves to 50% of normal or higher, patients usually have minimal or no symptoms, and at this point the frequency and intensity of bronchodilator therapy can be decreased and weaning from mechanical ventilation can ensue.

When status asthmaticus is resistant to therapy, it is likely that the expiratory airflow obstruction is caused predominantly by airway edema and intraluminal secretions. Indeed, some patients with status asthmaticus are at risk of asphyxia due to mucus plugging of the airways. In rare circumstances when life-threatening status asthmaticus persists despite aggressive pharmacologic therapy, it may be necessary to consider general anesthesia to produce bronchodilation. Isoflurane and sevoflurane are effective bronchodilators in this situation. Treatment of status asthmaticus is summarized in Table 2.6.

Management of Anesthesia

The occurrence of "severe" bronchospasm has been reported in 0.2%–4.2% of all procedures involving general anesthesia performed in asthmatic patients. Factors that are more likely to predict the occurrence of severe bronchospasm include the type of surgery (risk is higher with upper abdominal surgery and oncologic surgery) and the proximity of the most recent asthmatic attack to the date of surgery.

Several mechanisms could explain the contribution of general anesthesia to *increased* airway resistance. Among these are depression of the cough reflex, impairment of mucociliary function, reduction of palatopharyngeal muscle tone, depression of diaphragmatic function, and an increase in the amount of fluid in the airway wall. In addition, airway stimulation by endotracheal intubation, parasympathetic nervous system activation, and/or release of neurotransmitters of pain such as substance P and neurokinins may also play a role.
