TAR	thrombocytopenia absent radius
TDO	total dystrophic onychomycosis
TGF	transforming growth factor
TNF	tumor necrosis factor
TOWL	transonychial water loss
TTD	trichothiodystrophy
TUDDS	transungual drug delivery system
TUNEL	terminal deoxynucleotidyl transferase dUTP nick end labeling
US	ultrasonography
UV	ultraviolet
UVB	ultraviolet B
VEGF	vascular endothelial growth factor

Foreword

The fifth edition of *Baran & Dawber's Diseases of the Nails and their Management* is a lovely tribute to this fascinating and distinctive keratinized structure. Based upon the cumulative and vast experience of the authors, the book offers insights that are both well honed and practical. There is also an appreciation of the spectrum of clinical presentations of the various dermatological disorders that can affect the nail unit. Although overlapping clinical and histopathological features can be seen when a specific disease involves the skin versus the nail unit, this textbook succeeds in emphasizing those findings that are unique to the latter. An abundance of high-quality clinical photographs, combined with beautiful dermoscopic images and exceptional schematics, provide the reader with a wealth of useful information. I was particularly struck by the sophisticated nature of the discussion on trauma-induced nail changes, a topic that is sometimes erroneously viewed as mundane but has to be accurately diagnosed on a daily basis.

Patients with nail disorders, as well as the clinicians who care for those patients, will clearly benefit from the knowledge contained in these chapters, from logical approaches to diagnosis to effective therapeutic interventions. I speak for my colleagues when I say we are lucky to have such a body of worthwhile information so nicely organized for our consumption.

Jean Bolognia, MD
Professor of Dermatology
Yale School of Medicine

Preface

Diseases of the nail unit have fascinated physicians for centuries, beginning with Hippocrates. The nail is considered to be the window to the body, manifesting signs of internal disease and clues to one's health. Over time, more and more nail signs of skin disease and tumors arising in the nail apparatus have been studied and revealed.

The first edition of Drs. Baran and Dawber's textbook *Diseases of the Nails and their Management*, published in 1984, was a pioneering work. It became a much needed reference for physicians and students wanting a compendium on nail disease. With each edition, the text has become more comprehensive, making it the most complete and most read textbook on the subject – the authority on nail disease.

With the fifth edition, we are pleased to have increased our group of editors to include more diverse, experienced nail clinicians from Belgium and Italy. Textbooks, like this one, require unwavering, dedicated work from our contributors as well as from our publisher. Carefully chosen nail clinicians have authored each chapter, each of them a recognized leader in their subspecialty of nail disease. We wish to thank our publisher, Wiley, for their support in our requests and our endeavor to ensure that the text remains the recognized leader in nail disease. We especially want to thank Dr. Robert Baran for his enthusiasm and dedication in ensuring that each of the five editions has been thoughtful and complete. He and his wife, Nicole – a dedicated, though behind-the-scenes, editor – make an unbeatable team.

The fifth edition of *Diseases of the Nails and their Management* has been expanded to include new diseases and updated treatments, improved chapter organization, and new online video supplements. It is our sincere hope that the fifth edition of *Diseases of the Nails and their Management* broadens your knowledge of nail disease and becomes your primary reference on this subject, as it has ours.

CHAPTER MENU

Gross anatomy and terminology

Knowledge of nail unit anatomy and terms is important for clinical and scientific work [1, 2]. The nail is an opalescent window through to the vascular nail bed. It is held in place by the nail folds, origin at the matrix, and attachment to the nail bed. It ends at a free edge distally, overlying the hyponychium. These structures are illustrated in Figs 1.1–1.4. Definitions of the components of the nail unit are as follows.

- **Nail plate (nail)**: durable keratinized structure which continues growing throughout life.
- **Lateral nail folds**: the cutaneous folded structures providing the lateral borders to the nail.
- **Proximal nail fold (posterior nail fold)**: cutaneous folded structure providing the visible proximal border of the nail, continuous with the cuticle. On the undersurface this becomes the dorsal matrix.
- **Cuticle (eponychium)**: the layer of epidermis extending from the proximal nail fold and adhering to the dorsal aspect of the nail plate.
- **Nail matrix (nail root)**: traditionally, this can be split into three parts [3]. The dorsal matrix is synonymous with the ventral aspect of the proximal nail fold. The intermediate matrix (germinative matrix) is the epithelial structure starting at the point where the dorsal matrix folds back on itself to underlie the proximal nail. The ventral matrix is synonymous with the nail bed and starts at the border of the lunula, where the intermediate matrix stops. It is limited distally by the hyponychium.
- **Lunula (half moon)**: the convex margin of the intermediate matrix seen through the nail. It is paler than the adjacent nail bed. It is most commonly visible on the thumbs and great toes. It may be concealed by the proximal nail fold.
- **Nail bed (ventral matrix, sterile matrix)**: the vascular bed upon which the nail rests, extending from the lunula to the hyponychium. This is the major territory seen through the nail plate.
- **Onychodermal band**: the distal margin of the nail bed has a contrasting hue in comparison with the rest of the nail bed [4]. Normally, this is a transverse

band of 1–1.5 mm of a deeper pink (white) or brown (Afro-Caribbean). Its color, or presence, may vary with disease or compression, which influences the vascular supply (Fig. 1.5). Sonnex et al. [5] examined 1000 nails from thumbs and fingers in 100 subjects, alive and dead. In addition to clinical observation, they obtained histology from cadavers. Their findings

are summarized in Table 1.1. The onychodermal band represents the first barrier to penetration of materials beyond the nail plate. Disruption of this barrier by disease or trauma precipitates a range of further events affecting the nail bed. The white appearance of the central band represents the transmission of light from the digit tip through the stratum corneum and up through the nail. If the digit is placed against a black surface, the band appears dark.

- **Hyponychium**: the cutaneous margin underlying free nail, bordered distally by the distal groove (Fig. 1.6).
- **Distal groove (limiting furrow)**: a cutaneous ridge demarcating the border between subungual structures and the digit pulp.

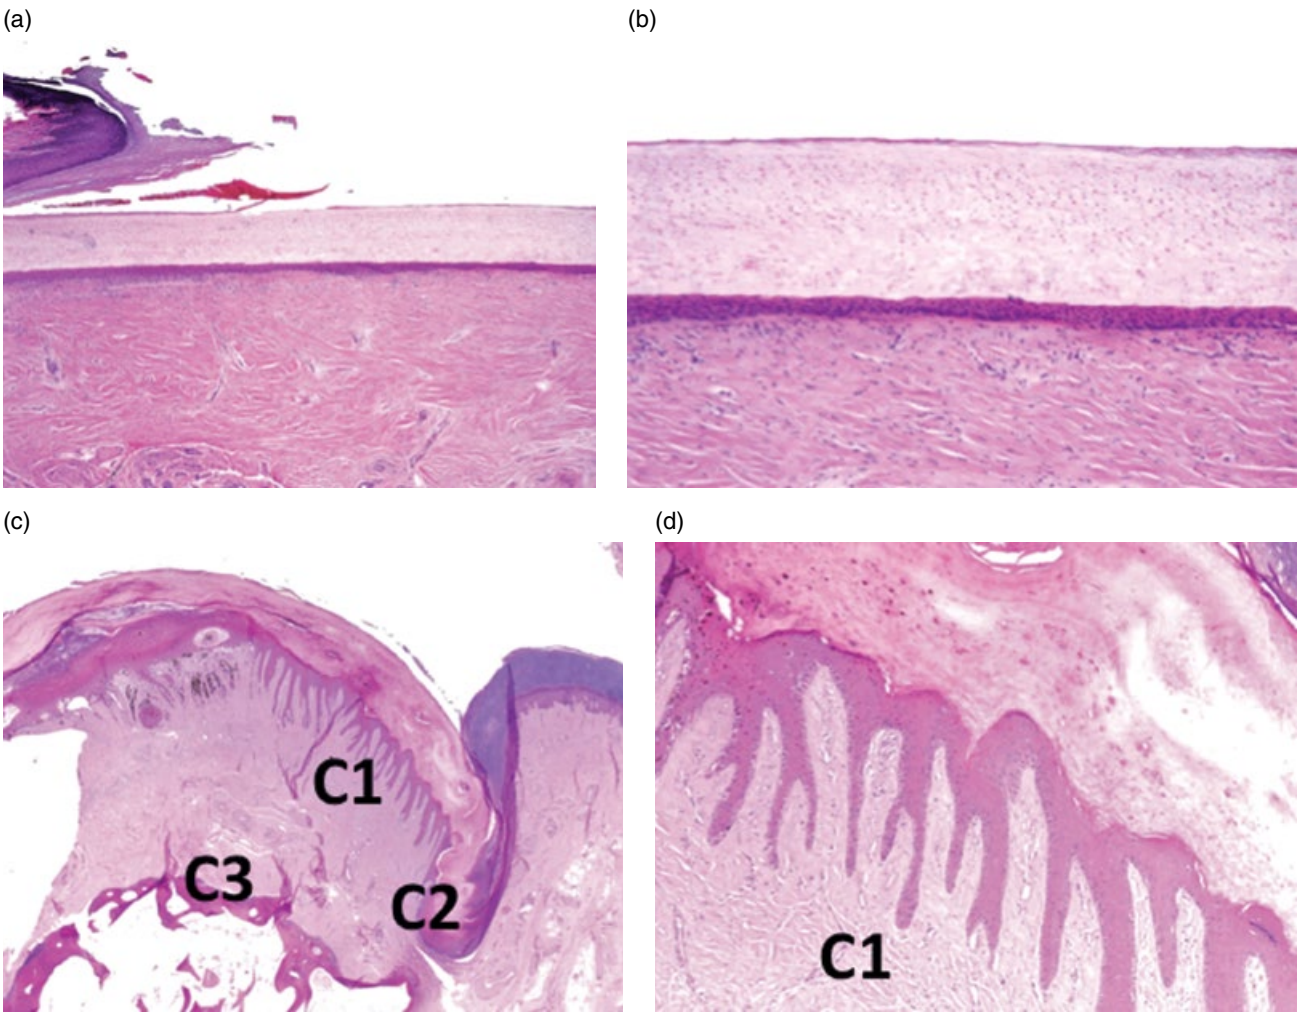

Figure 1.4 Distal nail matrix and nail bed in longitudinal excision. (a,b) Longitudinal view of the distal matrix and nail bed epithelium with overlying nail plate. (c,d) Transverse sections of the nail unit taken from an amputation for melanoma illustrating the nail bed longitudinal ridges in cross-section (C1), lateral nail groove (C2), and underlying phalanx (C3).

Embryology

Morphogenesis

8–12 weeks

Individual digits are discernible from the 8th week of gestation [3]. The first embryonic element of the nail unit is the nail anlage, present from 9 weeks as the epidermis overlying the dorsal tip of the digit. At 10 weeks, a distinct region can be seen and is described as the primary nail field. This almost overlies the tip of the terminal phalanx, with clear proximal and lateral grooves in addition to a well-defined distal groove. The prominence of this groove is partly due to the distal ridge, thrown up proximally, accentuating the contour. The primary nail field grows proximally by a wedge of germinative matrix cells extending back from the tip of the digit. These cells are proximal to both the distal groove and ridge. The spatial relationship of these two latter structures remains relatively constant as the former becomes the vestigial distal groove and the latter the hyponychium (Fig. 1.7).

13–14 weeks

Differential growth of the slowly developing primary nail field and surrounding tissue results in the emergence of overhanging proximal and lateral nail folds. Depending on the point of reference, the nail folds may be interpreted as overhanging [6] or the matrix as invaginating. By 13 weeks the nail field is well defined in the finger, with the matrix primordium underlying a proximal nail fold. By 14 weeks the nail plate is seen emerging from beneath the proximal nail fold, with elements arising from the lunula as well as more proximal matrix.

17 weeks to birth

At 17 weeks, the nail plate covers most of the nail bed and the distal ridge has flattened. From 20 weeks, the nail unit and finger grow in tandem, with the nail plate

abutting the distal ridge. This is now termed the hyponychium. The nail bed epithelium no longer produces keratohyalin, with a more parakeratotic appearance. By birth the nail plate extends to the distal groove, which becomes progressively less prominent. The nail may curve over the volar surface of the finger. It may also demonstrate koilonychia. This deformity is normal in the very young and a function of the thinness of the nail plate. It reverses with age.

Tissue differentiation

Keratins belong to the family of intermediate filament proteins. They are responsible for the tough resilient

Table 1.1 Clinical appearance of distal zones of the nail bed.

Zone	Subzone	Appearance
Free edge	–	Clear gray
Onychocorneal band		
I	Distal pink zone	0.5–2 mm distal pink margin, may merge with free edge
II	Central white band	0.1–1 mm distal white band representing the point of attachment of the stratum corneum arising from the digit pulp
III	Proximal pink gradient	Merging with nail bed

Figure 1.6 Distal nail unit in longitudinal excision. Onychodermal band (A) at the junction with the hyponychium (B) where a granular zone is again found along with acral compact stratum corneum.

quality of nail. They are found within the cytoplasm. There are 54 human keratin genes with their keratins divided into three categories:

1) epithelial keratins/genes
2) hair keratins/genes
3) keratin pseudogenes.

Schweizer et al. [7] devised the reclassification of keratins according to the system described below to accommodate the changing knowledge of keratins in the context of the previous system (Table 1.2).

The element of common ground between hair and nail biology is reflected in many shared keratins that lend physical characteristics to the tissue. Hence, although nail biology is not acknowledged in this scheme, where there is a designation of hair keratin, it is common for it also to be a nail keratin and for the higher level of sulfur amino acids in the keratin to afford a larger number of intramolecular cross-links and greater physical stability and strength.

Keratin synthesis can be identified in the nail unit from the earliest stages of its differentiation [8]. In 12- and

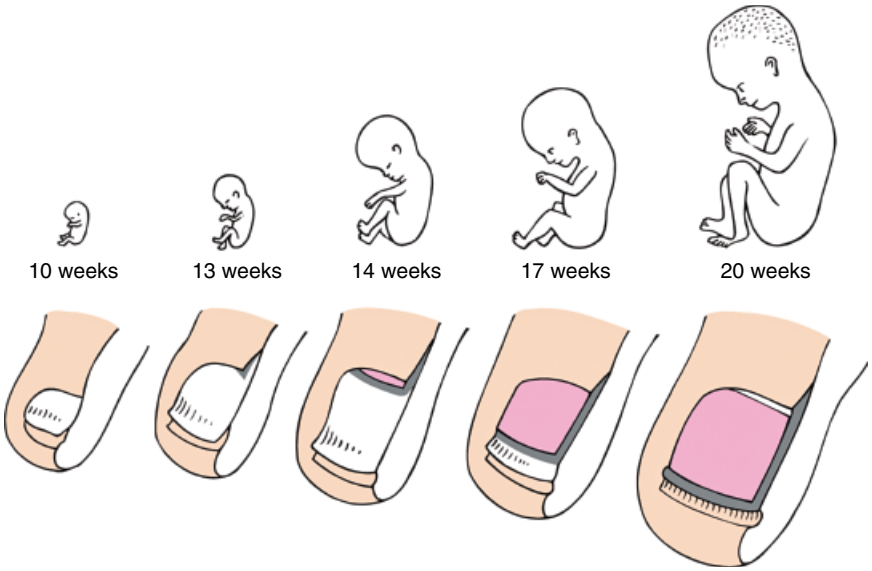

Figure 1.7 Embryogenesis of the nail apparatus. 10 weeks, The primary nail field can be seen with proximal, lateral, and distal grooves. The latter is accentuated by a distal ridge. 13 weeks, A wedge of matrix primordium moves proximally, with the invagination of the proximal nail fold above. 14 weeks, The nail plate emerges. 17 weeks, The nail plate covers most of the nail bed and the distal ridge starts to flatten. 20 weeks, The nail plate extends to the distal ridge, now termed hyponychium. Finger and nail grow roughly in tandem from now on. Fetuses are one-fifth of the actual size.

Table 1.2 Keratins and their former designations (www.interfil.org/proteinsTypeInII.php).

Category	Number range
Human type I epithelial keratins	9–28
Human type I hair keratins	31–40
Non-human type I epithelial and hair keratins	41–70
Human type II epithelial keratins	1–8 and 71–80
Human type II hair keratins	81–86
Non-human type II epithelial and hair keratins	87–120
Type II keratin pseudogenes	121–220
Type I keratin pseudogenes	221 →

13-week embryos, the nail–matrix anlage is a thin epithelial wedge penetrating from the dorsal epidermis into the dermis. This wedge is thought to represent the "ventral matrix primordium." By week 15, hard keratins are seen throughout the nail bed and matrix. This could have significance concerning theories of nail embryogenesis and growth, where debate exists as to the contribution made by the nail bed to nail growth [3, 9–12]. However, at 22 weeks, the layer of hard keratin-positive cells remains very thin in the nail bed, whereas it is considerably thickened in the matrix. In the adult nail, there have been reports of both the presence [13] and absence [8, 14–16] of hard keratins in the nail bed.

Histological observation at 13 and 14 weeks reveals parakeratotic cells just distal to this nail plate primordium staining for sulfhydryl groups. This contrasts to adjacent epithelium, suggesting the start of nail plate differentiation. This early differentiation represents matrix formation and Merkel cells have been detected in the matrix primordium of human fetuses between weeks 9 and 15 [17]. Merkel cells may play a role in the development of epidermal appendages and are detectable using monoclonal antibodies specific to keratin 20 (K20). Their role in ontogenesis would explain their disappearance from the nail matrix after week 22 [17]. However, this is not a universal finding, with an abundance of Merkel cells identified in the matrix of young adult and cadaver nail specimens in one study [18].

At the 13–22-week stage there is a coincident increase in the expression of hard keratins and the development of keratohyalin granules.

By 25 weeks, most features of nail unit differentiation are complete. Changes may still occur in the chemical constitution of the nail plate after this date. A decrease in sulfur and aluminum and a rise in chlorine have been noted as features of full-term newborns in comparison with the nail plate of premature babies [19]. An elevated aluminum level may correspond to bone abnormalities which lead to osteopenia.

Factors in embryogenesis

The nail plate grows from the 15th week of gestation until death. Many factors act upon it in this time and influence its appearance. Because it is a rugged structure, growing over a cycle of 4–18 months, it provides a record of the effects of these influences. To consider the different formative mechanisms, it is important to distinguish between:

- embryogenesis
- regrowth
- growth.

There is overlap between all these processes, with the main clues concerning embryogenesis deriving from fetal studies and analysis of congenital abnormalities.

Regrowth is the growth of the nail plate following its removal. This may be for therapeutic reasons or following accidental trauma with associated damage. Observation of this process adds to our understanding of both growth and embryogenesis. Growth is the continuous process of nail plate generation over a fully differentiated nail bed and hyponychium. Embryogenesis is the subject of this section.

In the chick limb bud formation, there is a complex interaction between mesoderm and ectoderm. Initially, the mesoderm induces the development of the apical ectodermal ridge (AER). The mesoderm then becomes dependent upon the AER for the creation of the limb. Removal of the AER results in a halt of mesodermal differentiation. Replacing the underlying mesoderm with mesoderm from another part of the limb primordium still results in normal differentiation [20]. However, the AER continues to be dependent upon the mesoderm, which must be of limb type. Replacement of limb mesoderm with somite mesoderm causes flattening of the AER. These morphogenetic interactions occur prior to cytodifferentiation [21]. In the human, cases of anonychia secondary to phenytoin [22] might implicate the drug at this stage, prior to 8 weeks. Drugs have been suggested as contributing to congenital nail dystrophies mainly affecting the index finger [23]. Attempts at characterizing a putative nail mesenchyme have involved ectopic nail studies in the newborn and mature nail unit. A CD10-positive population of dermal cells is located in the submatrix and nail bed dermis, which is common to the finding in mesenchyme of the hair follicle [24, 25]. In addition, one compartment has been reported as CD34 positive, which differentiates it from the nail bed where CD10 alone is found [26]. This zone of specialized submatrix tissue has been referred to as the onychodermis and can be identified in specialized magnetic resonance imaging [27].

Subsequent work on limb bud biology has explored the significance of the transcription factor LIMX1B in the mouse embryo limb formation. This factor is implicated in the dorsal/ventral polarity of the evolving limb and has been confirmed to have a similar role in humans. Loss of effective LIM1X function results in duplication of structures such that there might be a ventral ventral digit rather than dorsal ventral where the finger pulp is repeated on both sides of the digit [28]. The LIMX1B system also acts on genes determining development of the eye and urogenital tract, which is the basis for involvement of all these systems in nail–patella syndrome. In this pathology, the differentiation messages from the mesenchyme to the ectoderm appear to be communicated in a manner that might formally be described in observational limb bud experiments.

LIMX1B is thought to be mediated through the spondin pathway, where spondins are a family of proteins contributing to intracellular communication. In hereditary anonychia, there is a defect in R-spondin 4 secretion, where this protein would normally determine the activity of the Wnt/β catenin signaling system that is thought in turn to play a part in the initiation of nail unit formation [29–31]. Frizzled-6 is a Wnt receptor gene. In its absence a knockout mouse manifests a range of changes in the claw, including the downregulation of four hard nail keratins, K86, -81, -34, and -31, two epithelial keratins of significance in the nail unit, K6a and 6b, and transglutaminase-1. These changes are seen with an altered phenotype [32]. Similarly, where β catenin is deleted in knockout mice, nail formation and fingertip regeneration is completely lost, suggesting that the interruption of the Wnt signaling pathway has direct effects. Similar blockade of Wnt signaling results in extension of high Ki67 and K17 expression throughout the matrix, albeit without clear nail production [33]. R-spondin 2 is expressed in the AER in normal mouse limb development [34]. Mice bred to be deficient in this spondin have substantial congenital limb anomalies, with lack of phalangeal development and no nail unit [34]. Consistent with the model of mesenchyme inducing the overlying ectoderm, spondins have been identified in fibroblast cultures but not keratinocyte cultures [35].

Multiple other biological pathways appear relevant to the formation of a normal nail unit. Leucine-rich repeat-containing G protein-coupled receptor 5 and 6 (Lgr5 and -6) are part of the Wnt signaling pathway and associated with stem cell populations in different appendages. Lgr6 is found in the nail matrix and is thought necessary for nail unit regeneration following loss in mice [36]. The concept of a stem cell population is found in other appendages and in the nail it has been relatively difficult to establish such cell populations with confidence. Human embryos between 14 and 23 weeks assessed for expression of three candidate stem cell markers in the evolving nail unit demonstrate markers validated through their expression in the hair follicle bulge. These include PHLDA1 (Pleckstrin homology-like domain, family A, member 1), which is a protein-coding gene, and K15 and -19. These markers are not found in the matrix or nail bed, but have a transient expression in the proximal element of the ventral aspect of the proximal nail fold [37], where they are considered characteristic of stem cell differentiation [38]. A population of K15 label-retaining cells indicative of low turnover is found in a ring-like distribution around the nail root. They have potential to contribute to the nail plate or the nearby epidermis. Nail avulsion creates a wound environment that disposes them to the former, and this in turn appears influenced by bone morphogenetic factors [39]. Proximal matrix cells are characterized by expression of K17 in addition to the normal K14, while having a high proliferation rate as demonstrated through Ki67 and

exhibiting a colony-forming ability in vitro; also features that fit with the role of stem cells [33].

Other small molecules with relevance include histone deacetylase and the transcription factor FOX1 (Forkhead box N1). Reduction of histone deacetylase 1 and 2 in the K14 promoter biopathways in mice leads to abnormal appendage formation in embryogenesis. This affects hair follicles and claw formation, with dystrophic hyperpigmented claws. This suggests a role for histone deacetylase in ectodermal differentiation and morphogenesis [40]. FOXN1 (Forkhead box N1) is a transcription factor of significance in thymus epithelium and T-cell differentiation. It is also found in the nail matrix. Mutations with significance to other embryological defects and altered hair are also seen with nail dystrophy. Typically this is koilonychia, which structurally usually corresponds to thinning of the nail [41].

Transgenic mice with changes to the Akt gene demonstrate absent nail and distal bone. Akt is a serine/threonine protein kinase implicated in cell signaling [42]. Although the spondins reside in the mesenchyme and appear relevant to the interaction between mesenchyme and ectoderm, Akt is epithelial and is thought to play a part in the action of bone morphogenetic protein (BMP). BMP is part of the transforming growth factor (TGF)-β family of mediators. It is found in many different forms with a range of morphogenetic roles. In relation to the formation of the nail unit, it has been proposed that there is a two-way process whereby it is supportive of nail unit development, but equally that the nail unit plays a part in the regeneration of the distal phalanx when it is lost through trauma in infancy [43]; these processes may in part be mediated through BMP4.

Congenital abnormalities provide clinical examples of instances where the role of a BMP or similar factor appears central. Congenital onychodysplasia of the index fingers (COIF) is frequently associated with abnormalities of the terminal phalanges and interphalangeal joints [44]. The nail may be absent, small, or composed of several small nails on the dorsal tip of the affected finger. The bony abnormality varies, with the most marked change being bifurcation of the terminal phalanx on lateral radiographs [45]. However, a bony abnormality is not mandatory in this condition or other conditions with ectopic nail [46]. A normal nail may overlie an abnormal bone on other than the index finger [47]. COIF appears to demonstrate an association between abnormalities of bone and nail, rather than the presence of a strict relationship. It may represent a fault of mesoderm/ectoderm interaction at the stage when these layers are mutually dependent. It has been suggested that a vascular abnormality may provide the common factor between pathology in the two embryonic layers [47]. This would also be consistent with the part played by BMP in vascular development in embryogenesis [48]. If this is the case, it appears likely that any vascular abnormality arises due to a defect of patterned embryogenesis rather than a random event, given that a form of COIF can occur in the great toe of individuals with involved fingers [49].

An interpretation based upon a mutual mesodermal and ectodermal fault would fit with the observation of two cases of congenital anonychia and hypoplastic nails combined with hypoplastic phalanges [50] or brachydactyly [51, 52]. These cases were used as a foil for the suggestion of a mechanism of "bone-dependent nail formation." It might also be argued in reverse that the bone was dependent upon the nail.

Histological preparation

When submitting a nail unit specimen for histology, it is important to have some communication with the pathologist to whom you are submitting it, and for he/she in turn to guide the laboratory staff with respect to processing it. Such specimens can be difficult on multiple levels to optimally handle, and many pathologists lack familiarity with this category of specimen. It is helpful to orient it, depending on the type of specimen submitted [51]. For example, in a longitudinal excision, there is inherent orientation when the specimen is maintained in its natural longitudinal axis, and, in fact, the laboratory should be instructed to maintain this upon processing, without sectioning it in the usual transverse style (i.e. avoid "breadloafing") (Fig. 1.8). In a lateral longitudinal biopsy, one might however wish to indicate to the laboratory to embed on the edge away from the nail fold, as it might contain more helpful information. For more irregular shave and punch specimens and excisions, placing the delicate specimen on a piece of paper or nail template and inking on the paper near the distal end may also allow it to be sectioned, while maintaining some orientation and allowing the technician to know which surface is "up" (Fig. 1.8b). This also provides a mechanism to prevent thinner specimens from curling. Specimens containing nail plate and another containing soft tissue, for example a shave or punch, should be submitted in separate specimen bottles to facilitate processing, embedding, and cutting.

High-quality sections of the nail unit can be difficult to obtain. The nail plate is very hard and tends to shatter and fold in the course of routine histological processing. In biopsies containing nail plate and soft subungual and periungual tissue, the nail plate can be torn from the matrix and other adjacent structures by the microtome. Laboratories unused to nail histology will often have difficulty, may contact the clinician for advice, be slow to provide a result, and produce sections of suboptimal quality. Such problems can be diminished using a range of techniques to soften the nail plate. Some of them may be less practical and too harsh if there are soft tissue attachments requiring histological examination.

Nail softening techniques

Nail alone

There are a variety of different techniques to soften the nail plate. Some of them are not practical in the modern laboratory where speedy results are expected and the time available for technicians to spend on extra measures may be limited, but they will be discussed for historical perspective. Lewis [3] recommended routine fixation in 10% formalin and processing as usual. That is how most laboratories handle such specimens. Earlier methods employed fixation with potassium bichromate, sodium sulfate, or sodium bisulfite and water. The section is then decalcified with nitric acid and embedded in collodion. Alkiewicz and Pfister [53] recommended softening the nail with thioglycolate or hydrogen peroxide. Nail fragments are kept in 10% potassium thioglycolate at 37 °C for 5 days or in 20–30% hydrogen peroxide for 5–6 days. The nail is then fixed by boiling in formalin for 1 min before cutting 10–15 mm sections.

Although softening of nail clippings for histology is not mandatory, it is possible and may be helpful. Suarez et al. [54] suggest soaking the clipping for 2 days in a mix of mercuric chloride, chromic acid, nitric acid, and 95% alcohol. The specimen is then transferred to absolute alcohol, xylene, and successive paraffin mixtures, sectioned at 4 mm, and placed on gelatinized slides. An alternative method, described for preserving histological detail in the nail plate, entails fixation in a mix of 5% trichloroacetic acid and 10% formalin for the initial 24 h [55]. This is followed by a modified polyethylene glycol–pyroxylin embedding method. Ultrathin sections can be provided by embedding the nail in plastic such as 2-hydroxyethyl methacrylate [56].

In current clinical practice, one can use simpler and quicker methods with products containing combinations and dilutions of sodium hydroxide (NaOH), calcium hydroxide (CaOH), and thioglycolate [57–59]. Fabric softener, Mollifex Gurr (ethanol, methanol, acetone, glycerin, 4-hexylresorcinol; VWR International Ltd), and hand/dishwashing soap have all been utilized. A commercial nail-softening agent containing 17% potassium hydroxide (Fig. 1.9), Nail Prep (Stat Lab Medical Products, McKinney, TX, USA), can be used after nail processing, soaking for 15 min. It can also be used in between taking sections by application with a cotton swab. The author's histology team has also used this after an initial 4–6 h in 10% household ammonia prior to processing with excellent results. An over-the-counter depilatory agent, Nair (Church and Dwight, Ewing, NJ, USA) [60], containing CaOH, NaOH, and thioglycolate, can be diluted 2 : 1 with water and used to soak the nail for 2–3 h, and then it is processed as usual after rinsing. Many pathologists who work with nail specimens have their own approaches to handling such specimens depending also on local availability of reagents such as these [61]. Another simple method involves simply soaking the completed paraffin block in water, such as in a water bath in the histology laboratory, for 15 min before cutting to soften the nail plate.

Nail and soft tissue

In nail biopsies containing epithelium and/or soft tissue, more gentle methods of preparation are necessary, but the 17% potassium hydroxide and depilatory agents methods described above are also acceptable. The specimen can also be soaked in distilled water for a few hours

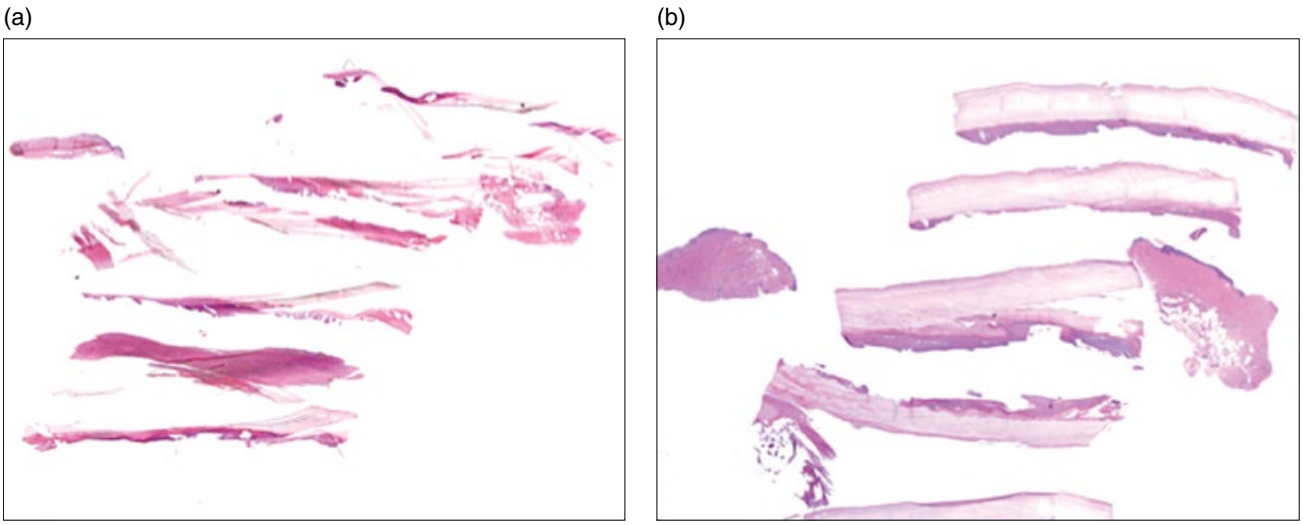

Figure 1.9 Use of nail softeners in tissue processing. (a) Nail plate and punch specimens, submitted together (not recommended) and without use of softeners. (b) Same specimens after softening at the time of cutting with 17% potassium hydroxide solution.

before placing in formalin [62]. Twelve hours in 10% formalin followed by 3 days in 3% phenol prior to embedding is reported to achieve good results [63]. After routine fixation and embedding, permanent wave solution (of the type used in hairdressing), thioglycolate, or 10% potassium hydroxide solution can be applied with a cotton swab to the surface of the paraffin block every two or three sections, similar to the methods above for nail plate. Lewin et al. [57] suggested applying 1% aqueous polysorbate 40 to the cut surface of the block for 1 h at 4 °C. Preparations containing acids, such as nitric acid used in decalcification solutions, should not be used on epithelium or soft tissue. They may interfere with other testing that one may want on such specimens, including some immunostains depending on intact DNA, such as proliferation markers, and molecular analysis [64, 65].

Sections will sometimes adhere to normal slides, but when there is nail alone the material tends to curl as it dries and may fall off. This means that it may be necessary to use gelatinized or 3-aminopropyltriethoxysilane (APES) slides. Albumin can also be used before placing the sections on the slide to improve adherence. Attention should be paid to avoiding folding of sections. Given the difficulty of obtaining high-quality sections, it may be necessary to cut at additional levels to maximize the chance of obtaining suitable sections.

Routine staining with hematoxylin and eosin is sufficient for most cases. Periodic acid–Schiff (PAS) and Grocott's silver stain can be used to demonstrate fungi; a blancophore fluorochromation selectively delineates fungal walls [66]. More recently, Gomori methenamine silver (GMS) stain has been advocated following pretreatment with chromic acid and sodium bisulfite [67]. There has been some recent discussion as to whether PAS or GMS staining is superior for identification of fungi in the nail, but they are probably equivalent, and PAS is much less labor intensive and less expensive to perform [68, 69]. Some of the more representative material in a nail sample for histology for fungus may be in the crumbling substance on the ventral aspect. This can be examined separately but requires a container such as a paper lens container to prevent dispersal of the material and to avoid problems with preparing sections [56]. Toluidine blue at pH 5 allows better visualization of the details of the nail plate [62, 63]. Fontana–Masson stain demonstrates melanin. Hemoglobin is identified using a modified diaminobenzidine reaction [70]. Prussian blue and Perl stains are not helpful in the identification of blood in the nail as they are specific to the hemosiderin product of hemoglobin breakdown caused by macrophages, which does not occur in the nail [53, 64, 65].

Masson–Goldner's trichrome stain is very useful to study the keratinization process, and Giemsa stain reveals slight changes in the nail keratin. These are not used widely in routine clinical practice.

Standard techniques for microwave antigen retrieval for immunohistochemistry, routine polymerase chain reaction studies, and terminal deoxynucleotidyl transferase dUTP nick end labeling (TUNEL) assays all appear feasible in combined soft tissue and nail specimens. Molecular analysis is also possible [71].

Polarization microscopy shows the regular arrangement of keratin filaments, and birefringence is said to be absent in disorders of nail formation such as leukonychia.

Routine histology

A longitudinal biopsy of the nail unit will yield a specimen with sampling of all the main histological zones of the appendage (Fig. 1.10). The cells of the nail matrix are distinct from the adjacent nail bed distally and the ventral

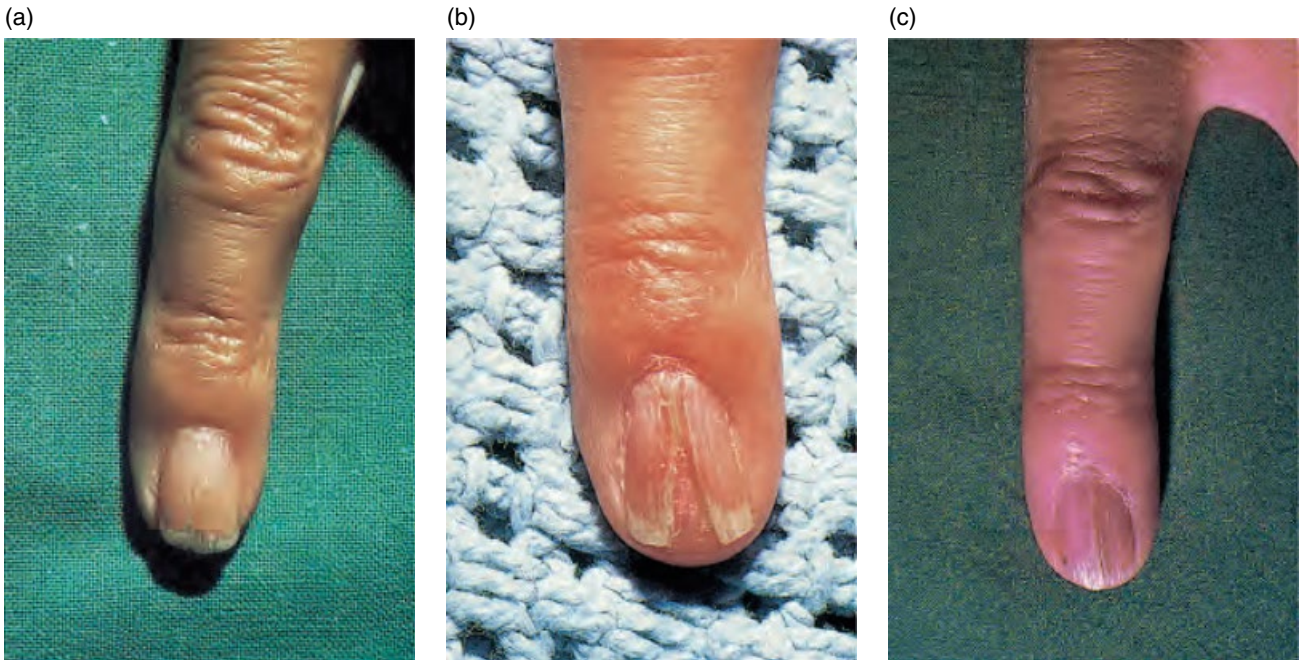

Figure 1.10 Longitudinal nail biopsy of Zaias. (a) Before biopsy; (b) 5 weeks after; (c) 3 months later.

surface of the nail fold, lying at an angle above. The nail matrix is the thickest area of stratified squamous epithelium in the midline of the nail unit, comparable with the hyponychium. There are longitudinally oriented epithelial ridges (unlike rete ridges) characteristically descending at a slightly oblique angle, their tips pointing distally. Laterally, the matrix ridges are less marked, whereas those of the nail bed and nail folds become prominent.

Unlike the overlying nail fold, but like the nail bed, the matrix has no granular layer (Fig. 1.11). The demarcation between overlying nail fold and matrix is enhanced by the altered morphology of the epithelial ridges. At their junction at the apex of the matrix and origin of the nail, the first matrix epithelial ridge may have a bobbed appearance like a lopped sheep's tail. PAS staining is marked at both the distal and proximal margins of the intermediate matrix (Fig. 1.12). Distally, there is often a step reduction in the epithelial thickness at the transition of the matrix with the nail bed. This represents the edge of the lunula.

Nail is formed from the matrix as cells become larger and paler and eventually the nucleus disintegrates. There is progression with flattening, elongation, and further pallor. Occasionally, retained shrunken or fragmented nuclei persist to be included into the nail plate. Lewis [3] called these "pertinax bodies." They can give an impression of the longitudinal progression of growth in the nail plate (Fig. 1.13).

Melanocytes are present in the matrix where they reach a density of up to 300/mm^2 [71–75]. This can also be expressed as the number of melanocytes per linear millimeter of matrix epidermis examined (Fig. 1.14). Figures for this are a mean of 7.5, median of 7.7, and range of 4–9 [76] (Table 1.3).

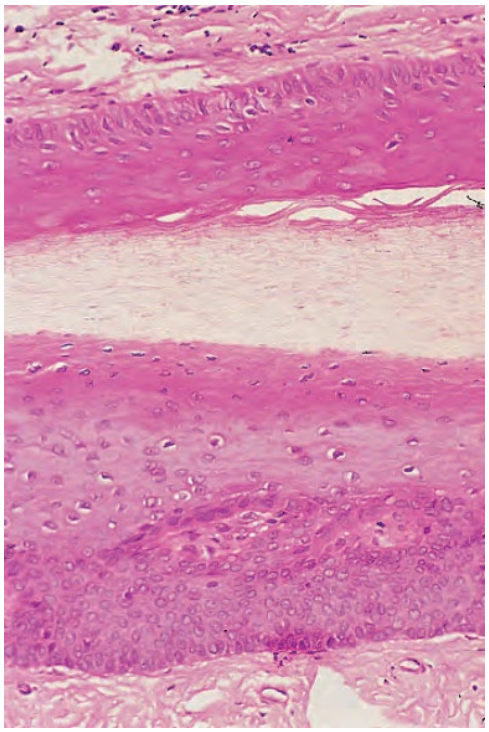

Figure 1.11 A granular layer is absent from the germinal matrix (lower part) and is variable on the ventral aspect of the proximal nail fold (upper part).

Dendritic cells are found in the epibasal layers and are most prominent in the distal matrix [73–75]. This point can be refined in terms of the functional status of the melanocytes. Cameli et al. [19] described melanocytes of the proximal matrix as being in a single compartment of largely dormant cells. Those in the distal matrix are in two compartments, with both a dormant and functionally differentiated population. Longitudinal melanonychia most commonly arises from pigment contributed to the nail plate by these differentiated distal melanocytes. Cameli et al. also defined a smaller population of nail bed melanocytes, with approximately 25% of the number found in the matrix, and none of these were differentiated in terms of 3,4-dihydroxy-L-phenylalanine (DOPA) staining. This differs from the observations of de Berker et al. [74], who noted that the nail bed lacked melanocyte markers.

The suprabasal location of nail matrix melanocytes can lead to difficulties in the interpretation of histological specimens obtained to exclude atypicality in instances of melanonychia, given that suprabasal scatter of melanocytes is a sign of atypia in normal epidermis. HMB-45, Melan-A, MiTF, and SOX-10 are useful markers of nail matrix melanocytes. S100, while helpful in desmoplastic melanoma at this and other sites with

respect to staining dermal melanocytes, is variable in its ability to stain matrix melanocytes. In spite of these difficulties in interpretation, melanoma is a relatively rare cause of nail unit pigmentation, although it may be necessary to exclude it histologically, particularly in white adults [73, 77, 78].

Melanin in the nail plate is composed of granules derived from matrix melanocytes [9]. Longitudinal melanonychia may be a benign phenomenon, particularly in Afro-Caribbean people: 77% of black people will have a melanonychia by the age of 20 and almost 100% by age 50 [79, 80]. The Japanese also have a high prevalence of longitudinal melanonychia, being present in 10–20% of adults [81]. In a study of 15 benign melanonychia cases in Japanese patients, they were found to arise from an increase in activity and number of DOPA-positive melanocytes in the matrix, not a melanocytic nevus [72]. A survey of fingers and toes of 2457 Chinese patients found none with melanonychia below the age of 20; 0.6% in those between 20 and 29; and 1.7% in those over 50 [82]. A French study of white patients found a 1.4% prevalence in the community and 12.6% prevalence in hospitalized patients [83]. The difference may have in part reflected different clinical sensitivity among community and hospital clinicians. In all studies, where mentioned, the thumb and great toe are the most commonly affected digit. Longitudinal melanonychia in white patients is more sinister; Oropeza [84] stated that a subungual pigmented lesion in this group has a higher chance of being malignant than benign.

There is only a thin layer of dermis dividing the matrix from the terminal phalanx. This has a rich vascular supply (see "Vascular supply") and an elastin and collagen infrastructure giving attachment to periosteum.

Electron microscopy

Transmission electron microscopy confirms that, in many respects, matrix epithelium is similar to normal cutaneous epithelium [85–91]. The basal cells contain desmosomes and hemidesmosomes and interdigitate freely. Differentiating cells are rich in ribosomes and polysomes and contain more RNA than equivalent cutaneous epidermal cells. As cell differentiation proceeds towards the nail plate, there is an accumulation of cytoplasmic microfibrils (7.5–10 nm). These fibrils are haphazardly arranged within the cells up to the transitional zone. Beyond this, they become aligned with the axis of nail plate growth.

Membrane-coating granules (Odland bodies) are formed within the differentiating cells. They are discharged onto the cell surface in the transitional zone and have been thought to contribute to the thickness of the plasma membrane. They may also have a role in the firm adherence of the squamous cells within the nail plate, which is a notable characteristic [91]. The glycoprotein characteristics of cell membrane complexes isolated from nail plate may reflect the constituents of these granules [92].

Mitochondria are degraded during the transitional phase, while RNA-containing ribosomes are evident up to the stage of plasma membrane thickening. Vacuoles containing lipid and other products of cytolysis are seen at the transitional stage. Dorsal matrix cells start to show nuclear shrinkage at this point, whereas the nuclei in the matrix remain intact to a higher level.

Electron microscopy has been used to examine the nail plate in detail in fungal disease [93], alopecia areata [94], connective tissue diseases [95], and psoriasis [96].

Regional anatomy

Nail matrix and lunula

For simplicity, the nail matrix (syn. intermediate matrix) will be defined as the most proximal region of the nail bed extending to the lunula. This is commonly considered to be the source of the bulk of the nail plate, although further contributions may come from other parts of the nail unit (such as the nail bed). Contrast with these other regions helps to characterize the matrix.

The matrix is vulnerable to surgical and accidental trauma; a longitudinal biopsy of greater than 3 mm width is likely to leave a permanent dystrophy [97] (Fig. 1.10). Once matrix damage has occurred, it is difficult to effectively repair it [98–100]. This accounts for the relatively small amount of histological information on normal nail matrix.

It is possible to make distinctions between distal and proximal matrix on functional grounds, given that 81% of cell numbers in the nail plate are provided by the proximal 50% of the nail matrix [101] and surgery to distal matrix is less likely to cause scarring than more proximal surgery. Clinically, the matrix is synonymous with the lunula, or half moon, which can be seen through the nail emerging from beneath the proximal nail fold as a pale convex structure. This is most prominent on the thumb, becoming less prominent in a gradient towards the little finger. It is rarely seen on the toes. The absence of a clinically identifiable lunula may mean that the vascular tone of the nail bed and matrix has obscured it or that the proximal nail fold extends so far along the nail plate that it lies over the entire matrix.

High-resolution magnetic resonance imaging identifies the matrix and dermal zones beneath [102, 103]. Drapé et al. [103] described a zone beneath the distal matrix where there is loose connective tissue and a dense microvascular network. It may be the presence of this network that accounts for the variable sign of red lunulae in some systemic conditions [104, 105]. However, the histological observations of Lewin [106] suggested that there is diminished vascularity and increased dermal

Box 1.1 Possible causes for the pale appearance of the lunula

- The surface of the nail is smoother and more shiny proximally.
- The thicker epidermis of the lunula obscures the underlying vasculature.
- The nail attachment at the lunula is less firm, allowing greater refraction and reflection at the nail–soft tissue interface.
- The underlying dermis has fewer capillaries in it.
- The underlying dermis is of looser texture.
- The matrix epithelium in the lunula has more nuclei than the nail bed, making it appear parakeratotic with an altered color.

collagen beneath the matrix contributing to the pallor, which helps identify the area. This has been confirmed in a more recent study utilizing injection of gelatinized Indian ink into amputation specimens [107]. The close association between the nail matrix and joint apparatus results in magnetic resonance imaging changes in the tendon sheath and matrix coincidentally [108] and may demonstrate changes in the matrix prior to the onset of any clinical nail disease [109].

The thinner epidermis of the nail bed may account for the contrast between the white and pink appearance of the lunula and bed, respectively [110]. Many suggestions have been made to account for the appearance of the lunula [75, 85, 106, 111] (Box 1.1).

Macroscopically, the distal margin of the matrix is convex and is easily distinguished from the contiguous nail bed once the nail is removed, even if the difference is not clear prior to avulsion. The nail bed is a more deep red and has surface corrugations absent from the matrix. At the proximal margin of the matrix, the contour of the lunula is repeated. At the lateral apices, a subtle ligamentous attachment has been described, arising as a dorsal expansion of the lateral ligament of the distal interphalangeal joint [112]. Lack of balance between the symmetrical tension on these attachments may explain some forms of acquired and congenital malalignment [113].

Nail bed and hyponychium

The nail bed extends from the distal margin of the lunula to the hyponychium. It is also called the ventral matrix, depending on whether or not you believe that it contributes to the substance of the nail plate (see "Nail growth"). Avulsion of the nail plate reveals a pattern of longitudinal epidermal ridges stretching to the lunula (Fig. 1.15). On the underside of the nail plate is a complementary set of ridges, which has led to the description of the nail being led up the nail bed as if on rails (Fig. 1.16). The small vessels

Figure 1.15 The epidermis of the nail bed has longitudinal ridges visible after nail avulsion.

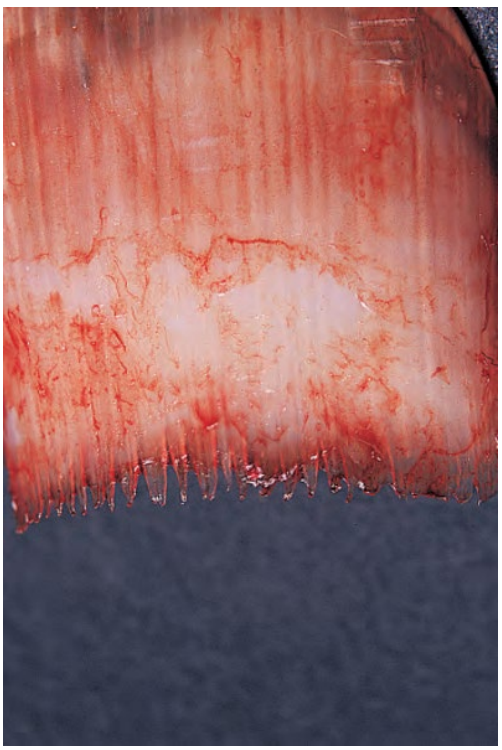

Figure 1.16 The undersurface of the nail plate shows longitudinal ridging that matches that seen on the nail bed. This pattern is lost at the margin of the lunula, where the nail is in continuity with the matrix from which it arises.

of the nail bed are orientated in the same axis. This can be demonstrated by using corrosion casting from cadaver digits [114] and is clinically manifested by splinter hemorrhages (Figs 1.17, 1.18), where heme is deposited on the undersurface of the nail plate and grows out with it. The free edge of a nail loses the ridges, suggesting that they are softer than the main nail plate structure. The nail bed also loses these ridges shortly after loss of the overlying nail. It is likely that the ridges are generated at the margin of the lunula on the ventral surface of the nail to be imprinted upon the nail bed.

The epidermis of the nail bed is thin over the bulk of its territory. It becomes thicker at the nail folds, where it develops rete ridges. It has no granular layer except in disease states. The dermis is sparse, with little fat, has firm collagenous adherence to the underlying periosteum, and has no sebaceous or follicular appendages. Sweat ducts can be seen at the distal margin of the nail bed using in vivo magnification (Fig. 1.19) [111].

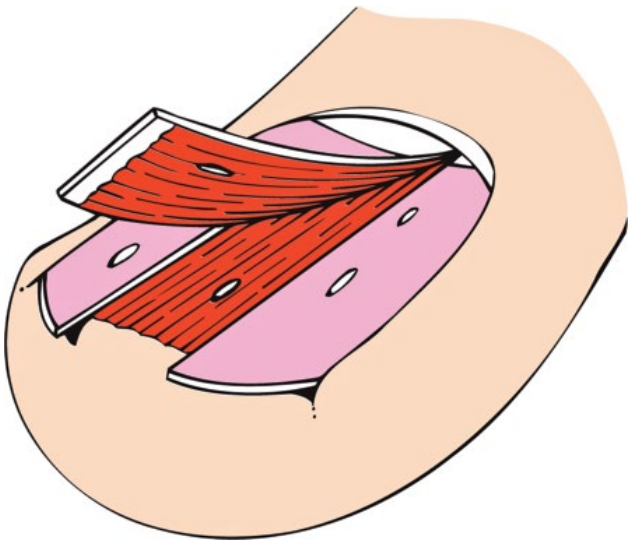

Figure 1.17 The appearance of splinter hemorrhages. Heme from longitudinal nail bed vessels is deposited on the underside of the nail plate. This grows out in the shape of a splinter.

Figure 1.18 The undersurface of the nail has dark-stained blood in the longitudinal grooves corresponding to splinter hemorrhages.

Figure 1.19 Sweat pores in the distal nail bed. Reproduced from Maricq et al. [111] with permission from Elsevier.

The hyponychium lies between the distal ridge and the nail plate and represents a space as much as a surface. Perrin [115] has described an analog of the hair follicle isthmus at the junction of the hyponychium and nail bed, referred to as the nail isthmus, leading on to the nail infundibulum, which he proposed would replace the term hyponychium. The distal ridge (see "Factors in embryogenesis") is seen from the 10th week of gestation onwards. The hyponychium and onychocorneal band may be the focus or origin of subungual hyperkeratosis in some diseases such as pityriasis rubra pilaris (see Table 1.8) or pachyonychia congenita.

The hyponychium can be extended into a pathological structure vulnerable to bleeding and pain with minimal trauma or nail clipping known as pterygium inversum unguis [116]. There is tough, fibrotic tissue tethering the free edge of the nail plate to the underlying soft structures. It is found in both congenital [117] and acquired forms [118]. The proposed etiology and patterns are various. Patterson [118] proposed that it was a combination of a genetic predisposition and microvascular ischemia.

The hyponychium and overhanging free nail provide a crevice which is a reservoir for microbes, relevant in surgery and the dissemination of infection. After 10 min of scrubbing the fingers with povidone–iodine, nail clippings were cultured for bacteria, yeasts, and molds [119]. In 19 out of 20 patients, *Staphylococcus epidermidis* was isolated, seven patients had an additional bacterium, eight had molds, and three had yeasts. These findings could have significance for both surgeons and patients. However, in a randomized trial of chlorhexidine scrub used with or without a nail brush, the nail brush did statistically diminish the number of colony-forming units obtained from the scrubbed hand [120].

The hand-to-mouth transfer of bacteria is suggested by the high incidence of *Helicobacter pylori* beneath the nails of those who are seropositive for antibodies and have oral carriage. Dowsett et al. [121] found that 58% of those with tongue *H. pylori* had it beneath the index fingernail, representing a significant ($p = 0.002$) association.

Nail folds

The proximal and lateral nail folds give purchase to the nail plate by enclosing more than 75% of its periphery. They also provide a physical seal against the penetration of materials to vulnerable subungual and proximal regions.

The epidermal structure of the lateral nail folds is unremarkable, and comparable with normal skin. There is a tendency to hyperkeratosis, sometimes associated with trauma. When the trauma arises from the ingrowth of the nail, considerable soft tissue hypertrophy can result, with repeated infection (such as ingrowing nails).

The proximal nail fold has three parts. Its upper aspect is normal glabrous skin, providing no direct influence upon the nail plate. At the point where its distal margin meets the nail plate, it forms the cuticle (eponychium). In health, the cuticle adheres firmly to the dorsal aspect of the nail plate, achieving a seal. Its disruption may be associated with systemic disorders (collagen vascular disease) or local dermatoses. In the latter, it may be the avenue for contact allergens or microbes. The ventral aspect of the proximal nail fold is apposed to the dorsal aspect of the nail. It contrasts with the adjacent matrix by being thinner, with shorter rete ridges, and having a granular layer. Keratins expressed in the proximal nail fold may differ on its dorsal and ventral aspects and can contrast with expression elsewhere in the nail unit [14] (see "Nail growth").

The proximal nail fold has significance in four main areas.

1) It may contribute to the generation of the nail plate through a putative dorsal matrix on its ventral aspect.
2) It may influence the direction of growth of the nail plate by directing it obliquely over the nail bed.
3) Nail fold microvasculature can provide useful information in some pathological conditions.
4) When inflamed, it can influence nail plate morphology as seen in eczema, psoriasis, habit–tic deformity, and paronychia.

The first two issues are dealt with in the section on nail growth (see "Nail growth"); the last two under vasculature (see "Vascular supply") and Chapter 14.

Immunohistochemistry of periungual tissues

Keratins

The most extensive immunohistological investigations of the nail unit have utilized keratin antibodies. The nail plate [13, 93], human embryonic nail unit [7, 13, 122], accessory digit nail unit [123, 124], adult nail unit [14, 46, 122, 125], and mouse claws [126] have all been examined (Table 1.4).

Table 1.4 Keratins in the nail unit.

Type II keratins	Type I keratins	Nail fold	Nail bed	Matrix
K1	K10	+	–	+
K5	K14	+	+	–
K6a		–	+	+
K6b	K16	–	+	+
	K17	–	–	+
K81 (Hb1)	K31 (Ha1)	–	–	+
K85 (Hb5)	K32 (Ha2)	–	–	+
K86 (Hb6)	K34 (Ha4)	–	–	+
	K38 (Ha8)	–	–	+
Keratins expressed transiently in embryogenesis				
	K19	-	-	+
	K15			+
Keratins known to have relevance to the nail unit through human or rodent disease genomics				
K75	Mice develop pachyonychia-like disease when they have mutations for this keratin. Also associated with tooth decay			
K74	Ectodermal dysplasia with woolly hair and nail defects			

Using monospecific antibodies, de Berker et al. [15, 123] detected K1 and K10 in a suprabasal location in the matrix and noted their absence from the nail bed (Fig. 1.20) (see "Nail growth" and "Nail plate"). K1 and K10 are "soft" epithelial keratins found suprabasally in normal skin [127] and are characteristic of cornification with terminal keratinocyte differentiation. Their absence from normal nail bed is reversed in disease where nail bed cornification is often seen, alongside development of a granular layer and expression of K1 and K10 [128]. The development of a granular layer in nail matrix and bed epithelium can be interpreted as a pathological sign in nail histology, seen in a range of diseases and probably associated with changes in keratin expression [129].

Ha-1 (K31), a "hard" keratin, is found in the matrix. K7 has been found at other sites in the nail unit and hair follicle, whereas Ha-1, detected by the monoclonal antikeratin antibody LH TRIC 1, is limited to the matrix of the nail (Fig. 1.21) and the germinal matrix of the hair follicle [16, 123]. Other hard hair/nail keratins have been highlighted as limited to the matrix where K85 (hHb5), K34 (hHa4), K81 (hHb1), and K86 (hHb6) have all been found within the conventional boundaries of the matrix. K19 is probably not found in the adult matrix [8, 15, 66].

[126]; regular, published studies. *KRT16 has not been studied in the mouse nail unit. #detected with AE13. Reproduced from Fleckman et al. [126] with permission of John Wiley and Sons.

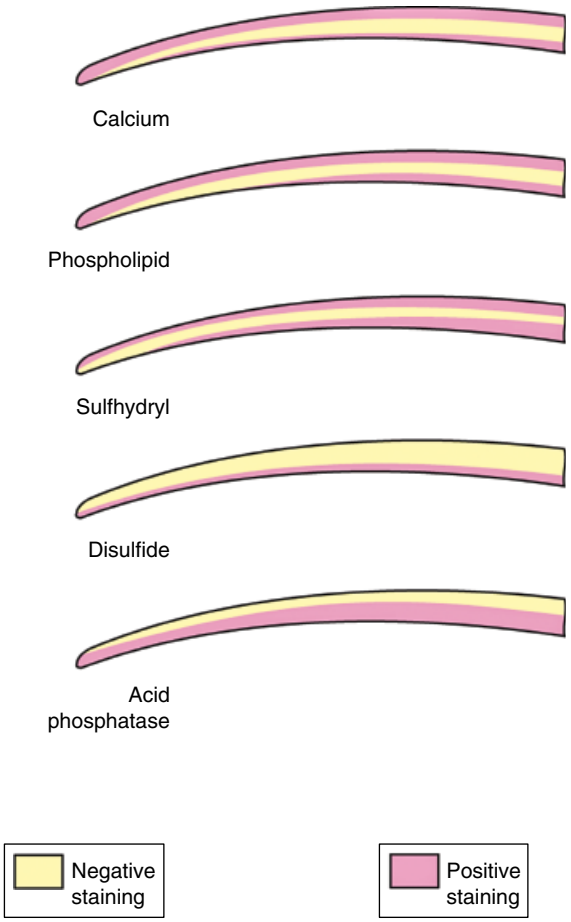

Figure 1.21 The histochemistry of the human nail plate (after Jarrett and Spearman [160]). Nail plates were sectioned and stained. Index, calcium; middle, phospholipid; ring, sulfhydryl; little, disulfide; thumb, acid phosphatase.

However, Moll et al. [8] did detect K19 at this site in 15-week embryo nail units. K19 is also found in the outer root sheath of the hair follicle and lingual papilla [14].

More recently, K6, -15, -16, -17, -18, and -19 have all been found at different subungual locations and phases in nail matrix development with a variety of attributed functions. K6, -16, and -17 have been implicated in innate immunity with the ability to trigger immunological responses [130]. K6 found beneath the normal nail is known to be necessary for the release of antibacterial peptides in response to *Pseudomonas aeruginosa*, a bacterium common in the subungual space of an onycholytic nail [131]. Human papillomavirus 16 is implicated in the development of subungual squamous cell carcinoma as well as carcinoma of the cervix. It complexes with K18 to result in its degradation, and this in turn may contribute to its pathogenicity as a carcinogen [132].The colocalization of hard and soft keratins within single cells of the matrix has been observed by several workers in bovine hoof [133] and human nail [15, 134, 135], suggesting that these cells are contributing both forms of keratin to the nail plate. This dual differentiation continues into in vitro culture of bovine hoof matrix cells [134]. Culture of human nail matrix confirms the persistence of hard keratin expression [135, 136].

Markers for K8 and K20 are thought to be specific to Merkel cells in the epidermis. Positive immunostaining for these keratins has been noted by Lacour et al. [137] in adult nail matrix and de Berker et al. [16] in infant accessory digits. Some workers have failed to detect Merkel cells and, while it seems likely that they are present in fetal and young adult matrix, it may be that the cells are less common or absent as people age [138].

Nail bed expression of K6a, -6b, -16, and -17 has significance, with the characterization of the underlying fault in some variants of pachyonychia congenita where abnormalities of nail bed keratin lead to a grossly thickened nail plate. Mutations in the gene for K17 have been reported in a large Scottish kindred with the PC-2, or Jackson–Lawler, phenotype [139, 140]. There is a cross-over with steatocystoma multiplex, where the same mutation of K17 may cause this phenotype, which appears to be independent of the specific K17 mutation [141–143]. Mutations in the gene coding for K6b produce a phenotype seen with K17 gene mutations [144]. Mutations in the K6a [145] and K16 [140] genes have been reported in PC-1, originally described as the Jadassohn–Lewandowsky variant of pachyonychia congenita.

Expression of K6, -16, and -17 extends beyond the nail bed onto the digit pulp and is thought to match the physical characteristics of this skin, which is adapted to high degrees of physical stress [146]. In particular, expression of K17 is found at the base of epidermal ridges, which might also support the idea that this keratin is associated with stem cell function.

It is important to recognize that the hard keratins responsible for the characteristics of nail tissue are the product of an interaction between underlying mesenchyme fibroblasts and the overlying epithelium. Hard nail keratins can be induced both in vivo and in vitro using nail matrix mesenchyme and non-nail epithelium [147, 148]. Induced expression of hard keratin is not the same as producing a nail, as the product of these experiments can be a poorly organized structure only recognizable as nail in immunohistochemical terms [149]. The specific nature of the nail mesenchyme may correspond to the presence of nail mesenchyme versican, where versican is a chondroitin sulfate proteoglycan and a member of the lecticans family [150].

Non-keratin immunohistochemistry

Involucrin is a protein necessary for the formation of the cellular envelope in keratinizing epithelia. It is strongly positive in the upper two-thirds of the matrix and elsewhere in the nail unit [151] and weakly detected in the suprabasal layers. Pancornulin and sciellin are also detected in the matrix [151]. The antibody HHF35 is considered specific to actin. It has been found to show a strong membranous staining and weak cytoplasmic staining of matrix cells.

In the dermis, vimentin was strongly positive in fibroblasts and vascular endothelial cells. Vimentin and desmin were expressed in the smooth muscle wall of some vessels. S100 stain, for cells of neural crest origin, revealed perivascular nerves, glomus bodies, and Meissner's corpuscles distally.

Filaggrin could not be demonstrated in the matrix by electron microscopy [14]. However, Manabe and O'Guin [152] have detected the coexistence of trichohyalin and filaggrin in monkey nail, located in the area they term the "dorsal matrix," which is likely to correspond to the most proximal aspect of the human nail matrix as it merges with the undersurface of the proximal nail fold. Kitahara and Ogawa [135] have identified filaggrin in the human nail in the same location, and Mlitz [153]and O'Keefe et al. [154] have found trichohyalin in the "ventral matrix" of human nail, which is synonymous with the nail bed. Manabe and O'Guin [152] noted that these two proteins coexist with K6 and K16, which are more characteristic of nail bed than matrix. It is argued that filaggrin and trichohyalin may stabilize the intermediate filament network of K6 and K16, which are normally associated with unstable or hyperproliferative states. When pathological mutations of the filaggrin gene and those for K16 coexist, the phenotype may be more severe than in the parent with the original isolated keratin gene mutation [155].

The plasminogen activator inhibitor type 2 has been detected in the nail bed and matrix, where, it has been argued, it may have a role in protecting against programmed cell death [156]. The basement membrane zone of the entire nail unit has been examined, employing a wide range of monoclonal and polyclonal antibodies [124]. Collagen VII, fibronectin, chondroitin sulfate, and tenascin were among the antigens detected. All except tenascin were present in a quantity and pattern indistinguishable from normal skin. Tenascin was absent from the nail bed, which was attributed to the fact that the dermal papillae are altered or considered absent (Table 1.5).

Nail plate

The nail plate is composed of compacted keratinized epithelial cells. It covers the nail bed and intermediate matrix and is curved in both the longitudinal and transverse axes. This allows it to be embedded in nail folds at its proximal and lateral margins, which provide strong attachment and make the free edge a useful tool. This feature is more marked in the toes than in the fingers. In the great toe, the lateral margins of the matrix and nail extend almost halfway around the terminal phalanx. This provides strength appropriate to the foot (Fig. 1.22). The nail appears as a layered structure when examined histologically with silver stain [3], with ultrasound [157], and using optimal coherence tomography [158] or scanning electron microscopy [159]. The different orientation of keratin fibrils within these layers appears to lend characteristics of both toughness and flexibility.

Lewis [3] described a silver stain that delineates the nail plate zones. Three regions of nail plate have been histochemically defined [160] (Fig. 1.21). The dorsal plate has a relatively high calcium, phospholipid, and sulfhydryl group content. It has little acid phosphatase

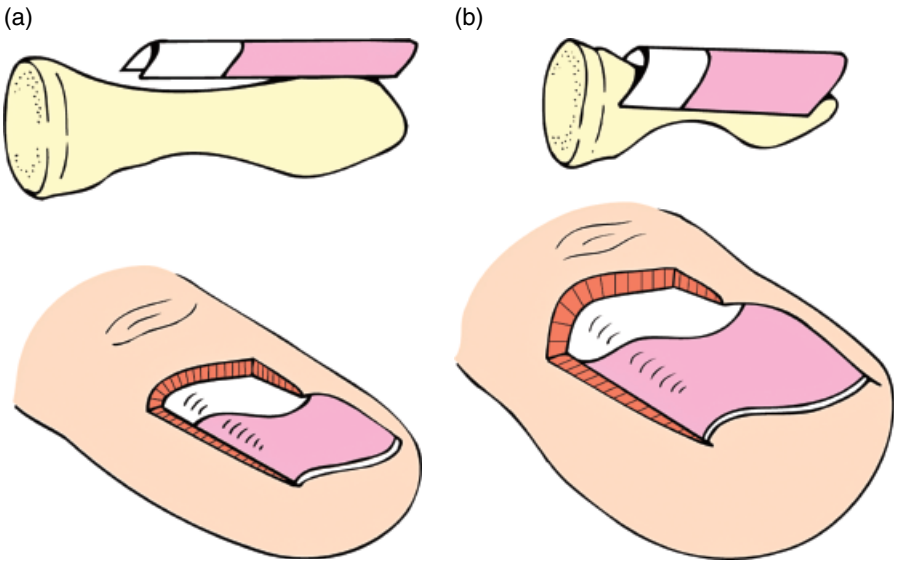

Figure 1.22 Nail plate association with soft tissue and bone in the finger and toe. (a) In the finger, the nail plate has modest transverse curvature and shallow association with soft tissues. (b) In the great toe, the nail plate has more marked transverse curvature and deep soft tissue association. This makes it appropriate to the foot but also accounts for the tendency to ingrow and the need for deep lateral extirpation at lateral matricectomy.

activity and is physically hard. The phospholipid content may provide some water resistance. The intermediate nail plate has a high acid phosphatase activity, probably corresponding to the number of retained nuclear remnants. There is a high number of disulfide bonds and low content of bound sulfhydryl groups, phospholipid, and calcium. Controversy suggests that the ventral nail plate may be a variable entity [161]. Jarrett and Spearman [160] described it as a layer only one or two cells thick. These cells are eosinophilic and move both upwards and forward with nail growth. With respect to calcium, phospholipid, and sulfhydryl groups, it is the same as the dorsal nail plate. It shares a high acid phosphatase and frequency of disulfide bonds with the intermediate nail plate. Nail plate integrity relies on the relationship of alpha coil and beta pleated sheets of keratin [161]. A combination of total reflection–Fourier transform infrared spectroscopy and X-ray photoelectron spectroscopy demonstrates that in psoriatic nail plate dystrophy the S–S bonds degrade to S–H and sulfite bonds with associated loss of alpha coils, increase in beta pleats random coils, and amorphous protein aggregation. These changes are seen with the loss of nail integrity and correlate with a more disordered incoherent appearance on scanning electron microscopy. In contrast, the disulfide bonds in onychomycosis appear to remain intact although there is disruption of cell–cell interaction and resulting increase in permeability [162].

Ultrasound examination of in vivo and avulsed nail plate suggests that it has the physical characteristics of a bilamellar structure [163]. There is a superficial dry compartment and a deep humid one. This has been given as evidence against the existence of a ventral matrix contribution to the nail plate. Synchrotron X-ray microdiffraction has been used to identify a trilamellar structure, where the dorsal and ventral fibers run transversely and the central fibers run in the longitudinal axis of the nail plate, occupying 70% of nail plate thickness. This lamination enhances nail resistance to tear and fracture forces in multiple axes [164].

The upper surface of the nail plate is smooth and may have a variable number of longitudinal ridges that change with age. These ridges are sufficiently specific to allow forensic identification and the distinction between identical twins [165]. Lyonization studies suggest that there is a sustained pattern of X-inactivation within the progenitor cells of single longitudinal nail ridges [166]. The ventral surface also has longitudinal ridges that correspond to complementary ridges on the upper aspect of the nail bed (see "Nail bed and hyponychium") to which it is bonded (Fig. 1.23). These nail ridges may be best examined using polarized light. They can also be used for forensic identification [167], as may blood groups from fragments of nail plate [168].

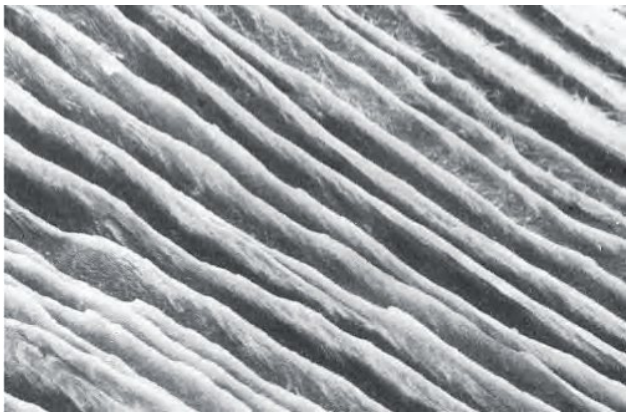

Figure 1.23 Scanning electron micrograph of the nail bed demonstrating longitudinal ridges.

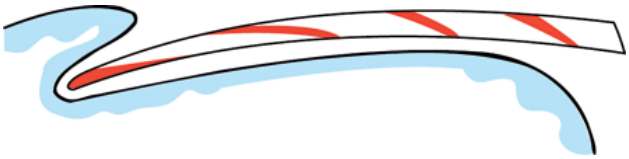

Figure 1.24 Shaded areas represent 7-day periods of nail growth, separated by 1 month, with transition of nail from horizontal to oblique axis over 4 months.

The nail plate gains thickness and density as it grows distally [11] according to analysis of surgical specimens. In vivo ultrasound suggests that there may be an 8.8% reduction in thickness distally [169]. A thick nail plate may imply a long intermediate matrix. This stems from the process whereby the longitudinal axis of the intermediate matrix becomes the vertical axis of the nail plate (Fig. 1.24). Other factors, such as the linear rate of nail growth [170], vascular supply, subungual hyperkeratosis, and drugs, also influence thickness. When comparing the transverse curvature of nails on dominant and non-dominant hands and between occupations with active high mechanical digit use (carpenters) and those with low (secretaries), it appears that the greater use and force applied through pinch strength results in a flatter nail [171]. The same is seen when comparing nails on the hemiplegic and contralateral hand in stroke victims [172]. A simple model in the adult hand is that the dominant hand has flatter nails than the non-dominant, which has been confirmed and is true when comparing men with women. It also holds with age, and power of grip does not always correspond to age and may reduce later in life [173]. A more global theory of forces and nail curvature attempts to explain the extremes of koilonychia and pincer nail through a mix of differential matrix growth and external mechanical molding forces. It requires the nail to be seen as a layered structure where the differences between the rate of movement of the dorsal and ventral nail results in curvature. It does not take

account of some of the underlying bone changes that also contribute to the change of nail shape over time. A mathematical model calculating the forces acting on the nail through adhesion, growth, and nail fold constraint can be used to explain the basis for pincer nails and ingrowing [174].

Transverse curvature and ultimately ingrowing can be influenced by the geometry of the relationship between the preterminal and distal phalanx. This will determine the pattern of forces on the distal and distolateral nail edge. Asymmetric forces tend to lead to nail deformity over time such that the risk of an ingrown toenail is greater in someone with hallux valgus [175]. A mathematical model calculating the forces acting on the nail through adhesion, growth, and nail fold constraint can be used to explain the basis for pincer nails and ingrowing [176].

In clinical practice, histology of the nail plate may be useful in a range of settings [177]. These include the diagnosis of psoriasis [178] and identification of fungal infections in culture-negative specimens [40, 46] (Fig. 1.25). It may also be used to identify the dorsoventral location of melanin in the nail clipping of a longitudinal melanonychia and hence allow prediction of the site of melanocyte activity in the intermediate matrix [179, 180]. Sonnex et al. [5] describe the histology of transverse white lines in the nail.

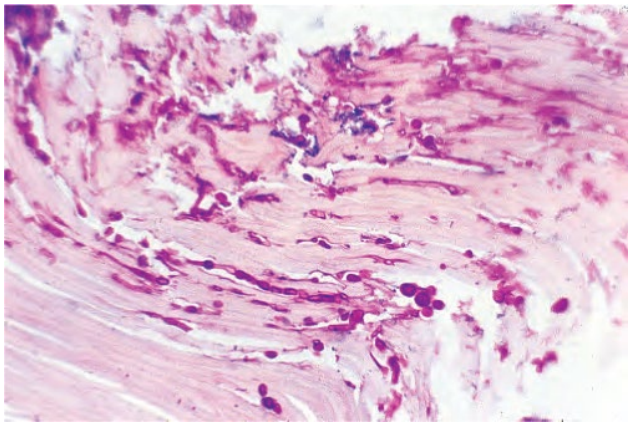

Figure 1.25 Fungal spores and hyphae can be seen in the stained section of a nail clipping taken from a nail with onychomycosis.

Germann et al. [181] utilized a form of tape stripping in conjunction with light microscopy to examine dorsal nail plate corneocyte morphology in disease and health. They found that conditions of rapid nail growth (psoriasis and infancy) resulted in smaller cell size. Nail keratin protein has been sampled and quantified using a similar tape-stripping method followed by colorimetric quantification [182].

Electron microscopy

Scanning electron microscopy has added to our understanding of onychoschizia [183, 184] as well as basic nail plate structure [185, 186]. In the normal nail, corneocytes can be seen adherent to the dorsal aspect of the nail plate. In cross-section, the compaction of the lamellar structure is visible. Both these features can be seen to be disrupted in onychoschizia following repeated immersion and drying of the nail plates. Scanning electron microscopy has also been used for assessing the location of fungal invasion into the nail plate [187, 188], although the lack of differential staining seen in routine light microscopy may mean that the latter is usually more useful.

Transmission electron microscopy has been used to identify the relationship between the corneocytes of the nail plate [91]. Using Thierry's tissue-processing techniques, material for the following description has been provided. Cells on the dorsal aspect ($34 \times 60 \times 2.2\,\mu m$) are half as thick as ventral cells ($40 \times 50 \times 5.5\,\mu m$), with a gradation of sizes in between. In the dorsal nail plate, large intercellular spaces are present corresponding to ampullar dilations (Figs 1.26, 1.27). These gradually diminish in the deeper layers and are absent in the ventral region. At this site, cells are joined by complete folds, membranes of adjacent cells appearing to penetrate each other to form "anchoring knots."

Cell membranes and intercellular junctions are easily discernible (Fig. 1.28). Even though at low magnification one can differentiate the dorsal and intermediate layers

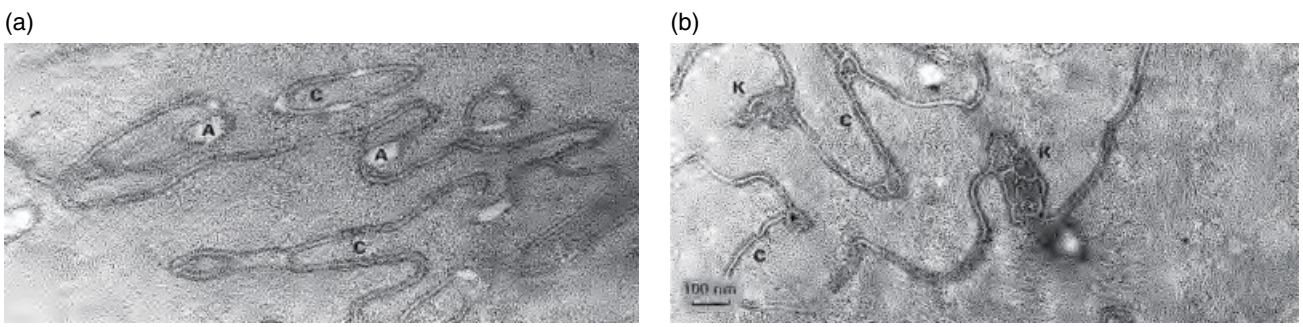

Figure 1.26 (a) Upper part of the nail plate showing ampullar dilatations (A). (b) Lower part of the nail plate showing anchoring knots (K). The only cell-to-cell coupling observed (C) is a desmosome. Courtesy of G. Achten.

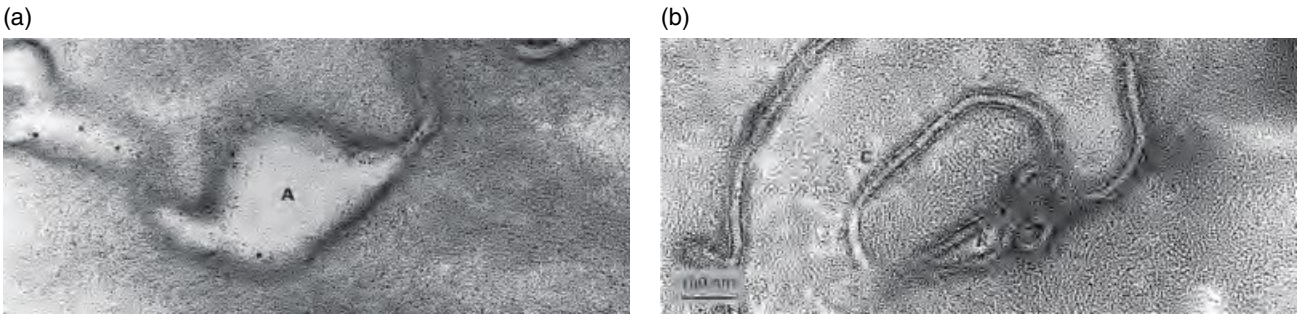

Figure 1.27 (a,b) Upper part of the nail plate as shown in Fig. 1.26, in greater detail. Courtesy of G. Achten.

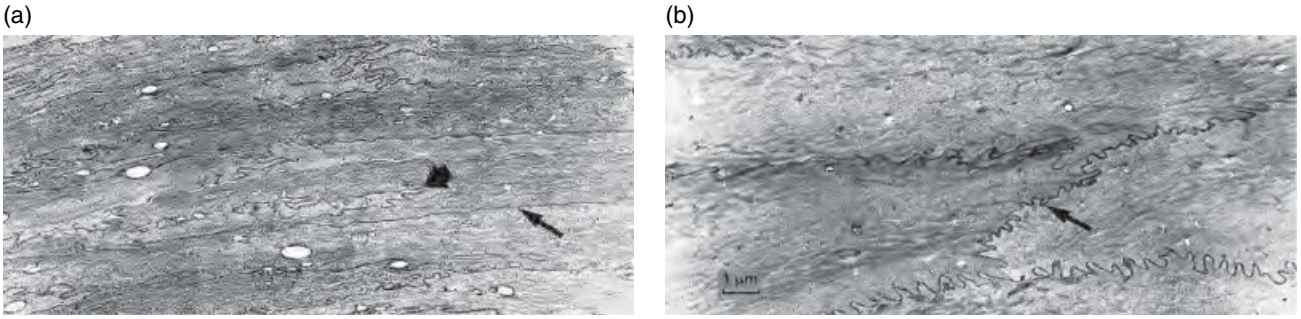

Figure 1.28 (a) Transmission electron micrograph of the upper part of the nail plate. The corneocytes are flattened and joined laterally by infrequent deep interdigitations (broad arrow). (b) The cell membranes between adjacent cell layers are discretely indented and in parts without invaginations: Thiery's technique. Courtesy of G. Achten.

of the nail plate, the exact boundary is unclear using transmission electron microscopy. Corneocytes of the dorsal nail plate are joined laterally by infrequent deep interdigitations. The plasma membranes between adjacent cell layers are more discretely indented, often with no invaginations (Fig. 1.28). In the deeper parts of the nail plate, the interdigitations are more numerous but more shallow (Fig. 1.28). No tight or gap junctions are seen in either of the major nail layers in this series [91] although they were identified previously by Forslind and Thyresson [185]. The intercellular material is homogeneous and separated from the cell membrane by two thin electron-dense lines. The space between the cell membranes varies from 25 nm to 35 nm (Figs 1.26–1.28). No complete desmosomal structures are seen.

Nail bed cells show considerable infolding and interdigitation at their junction with the nail plate cells (Fig. 1.29). They are polygonal and show no specific alignment. They are between 6 and 20 µm across and show neither tight nor gap junctions. They do, however, have desmosomal connections of the type seen in normal epidermis (Fig. 1.30).

Cryoelectron microscopy allows examination of fractured intracellular components in great detail without the artefacts normally associated with the chemical processing and coating of traditional electron microscopy techniques. Using this approach, the trichocyte intermediate filaments have been examined in rat vibrissae.

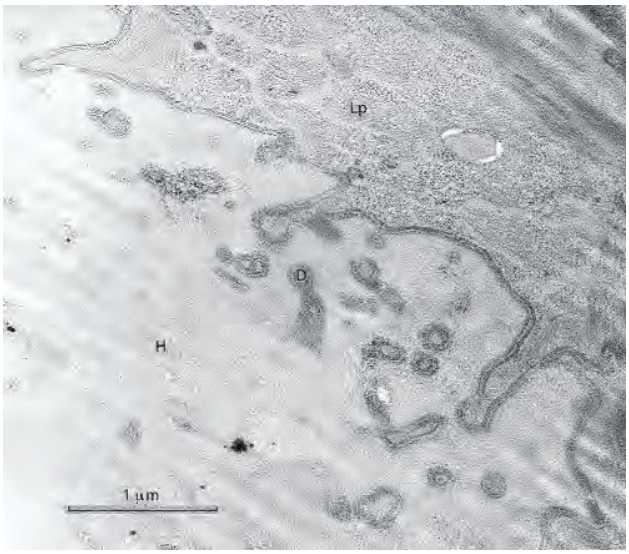

Figure 1.29 Corneocytes of the lowest part of the nail plate (Lp) sending out numerous digitations (D) penetrating the hyponychial nail bed cells (H). Courtesy of G. Achten.

Although these may differ from human nail in some respects, they will share the designation of hard keratins and so allow some transferable observations. The main observation was that the classic keratin fibril structure is the same, but a further arrangement of satellite proteins "decorates" the keratin. These proteins are suspected of

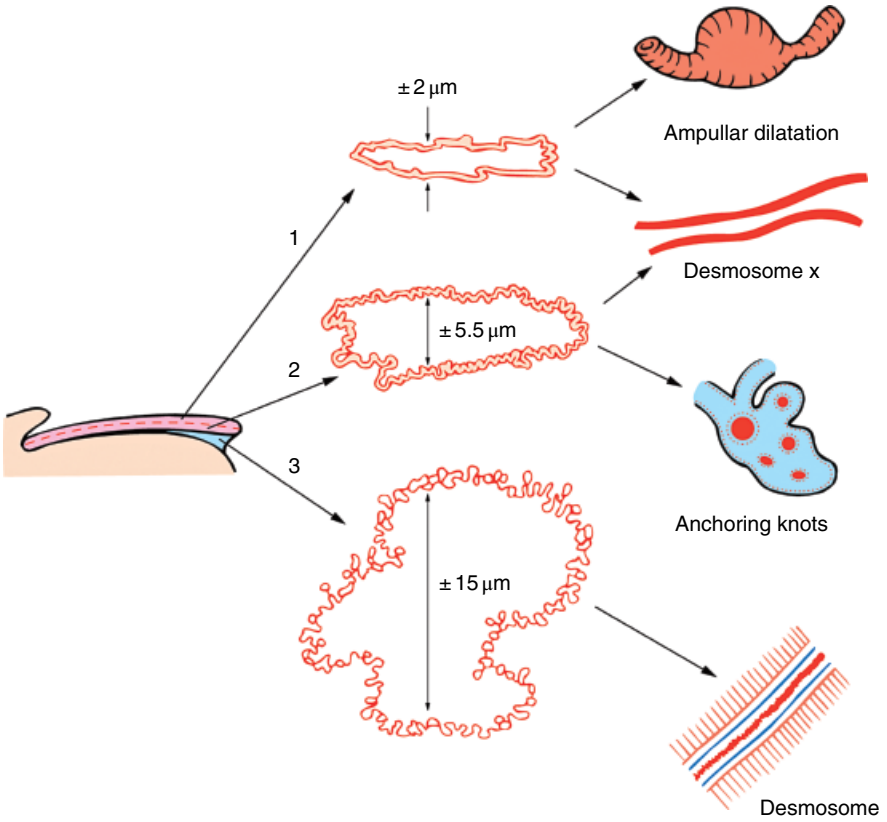

Figure 1.30 Intercellular junctions of the three parts of the nail: 1, upper plate; 2, lower plate; 3, hyponychial ventral nail with desmosome as seen by Thiery's technique. Courtesy of G. Achten.

being high sulfur amino acid proteins lending the keratin some of its rugged character [189], possibly through enhancing cross-linking between keratins and increasing their stability [190].

Using different preparation techniques, other workers have demonstrated other anatomical details. On the cytoplasmic side of the cell membranes of nail plate cells lies a layer of protein particles [84, 88, 191]. Other staining techniques suggest that the single type of intercellular bond described by Parent et al. [91] may be a spot desmosome [192].

Vascular supply

Arterial supply

The vascular supply of the finger is considered in detail here (Fig. 1.31). Many of the anatomical principles may be extended to the anatomy of the foot and toe, whilst details can be sought elsewhere [6].

The radial and ulnar arteries supply deep and superficial palmar arcades that act as large anastomoses between the two vessels. From these arcades extend branches aligned with the phalanges. Four arteries supply each digit, two on either side. The dorsal digital arteries are small and arise as branches of the radial artery. They undertake anastomoses with the superficial and deep

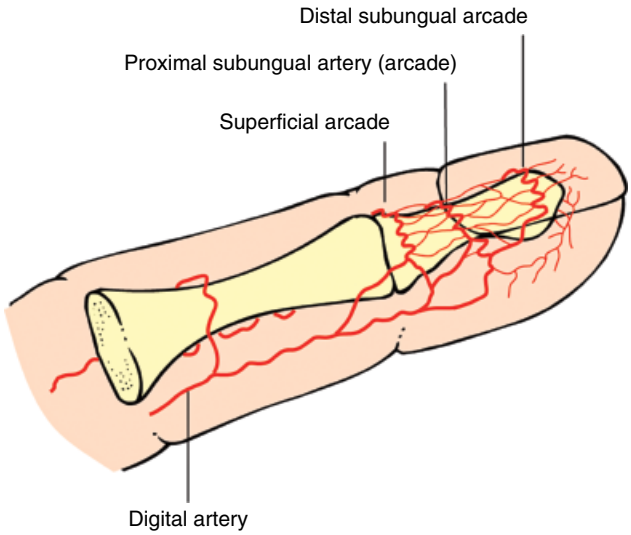

Figure 1.31 Arterial supply of the distal finger.

palmar arches and the palmar digital vessels before passing distally into the finger. The palmar digital arteries provide the main blood supply to the fingers. They receive contributions from the deep and superficial palmar arcades. Although paired, one is normally dominant [193]. They anastomose via dorsal and palmar arches around the distal phalanx. The palmar arch is located in a protected position, beneath the maximal padding of
